INDEX

NAME INDEX

- Abbot (Dr. C. G.), Solar Variation and the Weather, 705 ; Utilising Sunshine, 890
- Abbott (A.), Vocational Education in India, 1017
- Abetti (Dr. G.), translated by A. Zimmermann and F. Borghouts, The Sun: its Phenomena and Physical Features (*Review*), 662
- Ackermann (A. S. E.), elected an honorary fellow of the Society of Engineers (Inc.), 156
- Adams (Dr. W. S.), The 200-inch Telescope, 317
- Adamson (Prof. R. S.), The Vegetation of South Africa, 412 ; and Prof. T. A. Stephenson, Marine Biology in South Africa, 503
- Addison (Lord), A Policy for British Agriculture (*Review*), 779
- Adkins (J. N.), [P. Byerly and], Northern Californian Earthquakes during 1937, 209
- Adler (E.), Prof. H. v. Euler and G. Günther, Diaphorase I and II, 641
- Adler (Dr. F.), and Dr. H. von Halban, jun., Control of the Chain Reaction involved in Fission of the Uranium Nucleus, 793
- Adrian (Prof. E. D.), Localization of Activity in the Brain (Ferrier lecture), 691
- Ady (Miss P.), [Dr. J. Farquharson and], Magnetism and Polymerization, 1067
- Ahlfeld (F.), und J. M. Reyes, Mineralogie von Bolivien (*Review*), 48
- Aitmann (Prof. H.), awarded the Patron's medal of the Royal Geographical Society, 555
- Albert (O.), [A. Karlan and], Velocity of Catalysed Hydrogenation, 175
- Alexander (Dr. A. E.), elected a fellow of King's College, Cambridge, 572
- Alfvén (Dr. H.), Atomic Nuclei in Primary Cosmic Radiation, 435
- Alger (Prof. E. M.), presented with the Lealie Dana gold medal of the Association for Research in Ophthalmology and the St. Louis Society for the Blind, 469
- Alihan (Milla Alma), Social Ecology: a Critical Analysis (*Review*), 498
- Allchin (J. P.), [Dr. J. Newton Friend and], Presence of Less Common Elements in Rocks, 762
- Allen (Dr. J. F.), and Dr. H. Jones, Liquid Helium, 227
- Allen (late M. W.), [S. D. Townley and], Earthquakes of the Pacific Coast of U.S.A. (1769-1928), 820
- Allen (R. G. D.), conferment upon, of the title of reader in economic statistics by London University, 909
- Allibone, Bancroft and Innes, Million-volt X-Ray Tube, 755
- Alston (A. H. G.), The Kandy Flora (*Review*), 224
- Anderson (Ellen L.), Bibliography of the Housing and Equipment of School Libraries, 72
- Anderson (Dr. J.), [death], 712
- Anderson (Dr. J. S.), [Dr. H. J. Emsalus and], Modern Aspects of Inorganic Chemistry (*Review*), 742
- Anderson (Prof. W. B.), Physics for Technical Students in Colleges and Universities. Third edition (*Review*), 186
- Anderson (K. J. I.), A New Refraction Method for obtaining Photographic Records of Concentration Gradients, 720
- Andrade (Prof. E. N. da O.), and O. Dodd, Effect of an Electric Field on the Viscosity of Liquids, 26
- Andrew (L. W.), and A. Barrow, Comfort Heating by Gas, 1076
- Angel (F.), [H. Lhote and], Reptiles and Amphibians of the Sahara, 480
- Angwin (Col. A. S.), appointed Engineer-in-Chief of the Post Office, 677
- Appleton (Prof. E. V.), appointed secretary to the Committee of the Privy Council for Scientific and Industrial Research ; work of, 57 ; Terrestrial Magnetism and the Sunspot Cycle, 125 ; Composition and Temperature of the Upper Atmosphere, 1075 ; and R. Naismith, Scattering of Radio Waves in Polar Regions, 243
- Appleyard (Dr. E. T. S.), [death], 1057 ; J. R. Bristow and Dr. H. London, Variation of Field Penetration with Temperature in a Superconductor, 433
- Arber (Dr. Agnes), Miss Dorothea F. M. Partz, 590
- Archer (O. T.), conferment upon, of the title of reader by London University, 388
- Ardagh (J.), elected an associate of the Linnean Society of London, 847
- von Ardenne (M.), and others. Herausgegeben von Prof. F. Schröter, Fernsehen: die neuere Entwicklung insbesondere der deutschen Fernsichttechnik (*Review*), 98
- Armitage (A.), Copernicus: the Founder of Modern Astronomy (*Review*), 577
- Armstrong (A. L.), Palaeolithic Man in Northern England (Wilde lecture), 512
- Armstrong (Dr. E. F.), Synthetic Textiles, 236 ; presented with a Chevreul medal, 948
- Armstrong (late Prof. H. E.), proposed memorial to, 550
- Arnon (D. L.), 'Commercial' Water Culture of Plants, 467
- Arrow (G. J.), Dr. O. J. Gahan, 401
- Asada (T.), T. Okuda, K. Ogata and S. Yoshimoto, Preliminary report on the Masses of ^{12}C and ^{14}N , 797
- Aschaffenburg (Dr. R.), A Gold Sol Test for Bovine Mastitis, 523
- Ashbel (Dr. D.), Foam on the Dead Sea, 468
- Ashby (Prof. E.), [Dr. Helen Ashby, Dr. H. Richter, Dr. J. Bärner and], German-English Botanical Terminology (Englisch-Deutsche Botanische Terminologie), (*Review*), 421
- Ashby (Dr. Helen), Prof. E. Ashby, Dr. H. Richter and Dr. J. Bärner, German-English Botanical Terminology (Englisch-Deutsche Botanische Terminologie), (*Review*), 421
- Ashley (Sir Percy), elected chairman of the British Standards Institution, 976
- Ashmead (J.), Specific Heat of Copper Sulphate below 1°K , 853
- Astapowitsch (L. S.), Meteoric Falls in the U.S.S.R., 376
- Astbury (Dr. W. T.), and Miss Florence O. Bell, Structure of Proteins, 280
- Aston (Dr. F. W.), Discrepancies in the Isotopic Weight of ^{12}C , 797
- Astrup (T.), [F. Haurowitz and], Ultra-violet Absorption of Genuine and Hydrolysed Protein, 118
- Atchley (late Shirley Clifford), Wild Flowers of Attica (*Review*), 352
- Aten, jun. (A. H. W.), [F. A. Heyn, Dr. O. J. Bakker and], Transmutation of Uranium and Thorium by Neutrons, 516 ; Transmutation of Thorium by Neutrons, 679
- Athavale (V. T.), and S. K. K. Jaitkar, Hydrogenation of Oils by the Continuous Process, 255
- Atkins (Dr. B. E.), [Dr. A. B. D. Cassie, G. King and], Thermo-static Action of Textile Fibres, 163
- Auger (P.), R. Mase, P. Ehrenfest and A. Fréon, Large Cosmic Ray Showers, 481
- Austen (A. E. W.), and W. Hackett, Electronic Break-down in Solid Dielectrics, 637

- Austin (J.), Disposal of Offal (Benjamin Ward Richardson lecture), 514
- Axelrod (A. E.), and Prof. O. A. Elvehjem, Effect of Nicotinic Acid Deficiency on the Cozymase Content of Tissues, 281
- Ayyar (Dr. T. V. Ramakrishna), Insects and Their Role in Indian Agriculture, 530
- Babcock (H. D.), Recent Observations of Sunspot Spectra, 307
- Bacoco (M.), A New Mysid Crustacean from the Black Sea, 768
- Bacharach (A. L.), with a Preface by Prof. J. O. Drummond, Science and Nutrition (*Review*), 263; Vitamins (*Review*), 659
- Baoq (Dr. Z. M.), [Prof. A. Szent-Györgyi, M. Goffart and], A Humoral Transmission of Muscular Contraction in the presence of Veratrine, 522
- Baddiley (J.), award to, of the Perkin medal of the Society of Dyers and Colourists; work of, 324
- Badoux (P.), L'Antenne Rayonnante (*Review*), 920
- Bagehee (Dr. K. D.), Indian Forest Mycology, 529
- Bailey (Prof. E. B.), du Toit's Our Wandering Continents (*Review*), 139
- Bailey (K. O.), Retardation of Chemical Reactions (9), 905
- Bailey (S. K.), Roosevelt and His New Deal, 371
- Bailey (R.), Use of the Infra-red in the Study of Minerals, 445
- Baker (F.), Role of Fungi and Actinomycetes in the Decomposition of Cellulose, 522
- Baker (Dr. J. R.), Increasing Winter Egg-production in Spain More Than a Hundred Years Ago, 477
- Baker (W.), Synthesis of 5:6-Dihydroxyflavone and the Structure of Primetin, 900
- Baker (W. E. Watson), elected president of the Quekett Microscopical Club, 469
- Bakker (Dr. O. J.), [F. A. Heyn, A. H. W. Aten, jun. and], Transmutation of Uranium and Thorium by Neutrons, 516; Transmutation of Thorium by Neutrons, 679
- Balavoine (P.), Variation of Composition of the Water of Lake Geneva, 910; Observations on Snow, 911
- Baldinger (E.), and Dr. P. Huber, Disintegration of Nitrogen by Fast Neutrons, 894
- Baldwin (F. G. O.), The History of the Telephone in the United Kingdom. Cheaper edition (*Review*), 185
- Balfour (Prof. Henry), [obituary article], 291; Spinners and Weavers in Anthropological Research (Fraser lecture), 295
- Ballard (Prof. S. S.), Spectrographic Analysis of Three Arthropods, 979
- Barcroft [Allibone, Innes and], Million-volt X-Ray Tube, 755
- Barcroft (D.), [F. Birch and], Effect of Pressure on the Rigidity of Rocks, 769
- Banga (L.), S. Ochoa and Prof. R. A. Peters, Active Form of Vitamin B₁ in Tissues, 764
- Banister (Dr. H.), and O. L. Zengwill, Experimentally Induced Restricted Paramnesias, 438
- Bank (O.), [H. G. Bungenberg de Jong and], Behaviour of Microscopic Bodies consisting of Bio-colloid Systems Suspended in an Aqueous Medium (8), 489; (4, 5), 1079
- Banks (Dr. T. E.), [Dr. M. E. Nahmias, Prof. F. L. Hopwood, W. H. Rann, L. G. Grimmett and], Apparent Existence of a Very Penetrating Radiation from Radium and (Radium + Beryllium), 1085
- Banue (Prof. E.), Lehrbuch der organischen Geographie: Vorschule und Einführung in das Studium (*Review*), 137
- Bentley (W.), and P. Scherrer, Anomaly of the Specific Heat of Potassium Dihydrogen Phosphate at the Upper Curie Point, 980
- Barbier (D.), and D. Ohalange, Night Temperature of the Upper Layers of the Atmosphere, 951
- Barolay (R. S.), and W. O. Kermack, Changes of Average Maternal Age, 804; Fertility of Scottish Married Women, with Special Reference to the Period 1926-1935, 950; Fertility Rates of Scottish Married Women, 1028
- Barcroft (Sir Joseph), elected a foreign associate of the U.S. National Academy of Sciences, 888
- Barger (Prof. G.), [death], 56; [obituary article], 107
- Baricau (R. E.), [J. W. Stout and], Resistance of Gold and Silver at Low Temperatures, 647; [W. F. Giauque, J. W. Stout and], Viscosities of Liquid Helium, 769
- Barkas (W. W.), Moisture in Wood, 250
- Barker (Prof. B. T. P.), and others, Fruit-Juices and Syrups, 651
- Barker (Prof. E.), Impacts of Science on Society, 947
- Barlee (J. S.), Waxy Secretion of Some Glaucous Cedar Leaves, 175
- Barnard (C. C.), Periodicals for Medical and Scientific Libraries, 297
- Bärner (Dr. J.), [Dr. Helen Ashby, Prof. E. Ashby, Dr. H. Richter and], German-English Botanical Terminology (Englisch-Deutsche Botanische Terminologie (*Review*), 421
- Barnes (A. S.), Eoliths, 593
- Barnes (Dr. B.), and C. C. Hentschel, Terminology in Biology, 478
- Barnóthy (J.), and M. Forró, Influence of Meteorological Factors upon the Intensity of Cosmic Ray Showers, 889
- Baron (O.), Use of Light Metals in the Composition of Explosives with an Ammonium Nitrate Base, 826
- Barrow (A.), [L. W. Andrew and], Comfort Heating by Gas, 1076
- Barrow (W.), resignation of the pro-chancellorship of Birmingham University, 306
- Barry (V. O.), Constitution of Laminarin: Isolation of 2:4:6-Trimethylglucopyranose, 175
- Bassett (Prof. H.), A Guide to Chemical Laboratory Practice: for Beginners (*Review*), 960
- Barton, jun. (W. H.), and J. M. Joseph, Starcraft (*Review*), 919
- Beau (Prof. N. M.), Physiological Research in India, 531
- Baten (Prof. W. D.), Elementary Mathematical Statistics (*Review*), 960
- Bates (Dr. G. H.), Colchicine-induced Polyploidy in Nature, 643
- Bawden (F. O.), and F. M. L. Sheffield, Intracellular Bodies of Plant Viruses, 1029
- Bayliss (Prof. N. S.), and A. L. G. Rees, Effect of Foreign Gases on the Continuous Absorption Spectrum of Bromine, 560
- Beach (E. F.), and A. White, Synthesis of Cystine in Rats, 902
- Beale (H. P.), nominated pro-chancellor of Birmingham University, 306
- Beale (G. H.), G. M. Robinson, Sir Robert Robinson and R. Scott-Moncrieff, Flower Colour in the Sweet Pea, 862
- Beard (Dr. George Miller), Centenary of the birth of; work of, 753
- Beard (J. W.), H. Finkelstein and R. W. G. Wyckoff, pH stability of Elementary Bodies of Vaccinia, 382
- Beattie (Mrs. E. M.), Visual Threshold Values, 38
- Beaumont (Dr. G. E.), Diets for Diabetes; arranged in Menu Form (*Review*), 425
- Beaver (S. H.), Geographical Aspects of Current Problems, 169
- Béclère (Dr. Antoine), [obituary article], 591
- Béguin (A. E.), [Dr. O. E. Georgi and], Heterauxin Production by Efficient and Inefficient Strains of *Rhizobia*, 25
- Béhounek (O.), [F. Schacherl and], Copper Sulphate Pentahydrate, 527
- Belinfante (F. J.), A New Form of the Baryteron Equation and some Related Questions, 201
- Bell (Miss Florence O.), [Dr. W. T. Astbury and], Structure of Proteins, 280
- Bell (R. W.), [Sir Gwilym Gibbon and], History of the London County Council; 1889-1939 (*Review*), 657
- Bellamy (Ethel F.), Epicentres of Earthquakes, 1913-1932, 504
- Benham (Prof. W. B.), *Mauicetus*: a Fossil Whale, 765
- Benioff (H.), Rate of Faulting near an Earthquake Epicentre, 124

- Benjamin (Dr. M.), and R. O. Jenkins, Migration of Barium on Molybdenum, 279; Surface Structures of Possibly Atomic Dimensions using Autoelectronic or 'Field' Emission from Fine Metal Points, 589
- Bennet (G. A.), [E. J. Irons and], A Falling-weight Time Switch, 567
- Bent (A. C.), North American Birds of Prey, 299
- Bentham (R.), awarded the Murchison grant of the Royal Geographical Society, 555
- Bentley (Prof. B. H.), appointed emeritus professor in Sheffield University, 308
- Berg (O. P.), [J. R. Totter and], Optical Isomerism and Growth, 819
- Berg (Dr. L. T.), work of, 150
- Bergmann (Dr. E.), [Prof. V. Henri and], Ultra-violet Absorption Spectrum and Chemical Reactivity of some Substituted 9-Vinyl-Phenanthrenes, 278; [Dr. G. Weissmann, Dr. Y. Hirschberg and], Hydrolytic De-amination of Amino-Acids, 723
- Bergmann (Prof. L.), translated by Dr. H. S. Hatfield, Ultrasonics and Their Scientific and Technical Applications (Review), 415
- Bergmann (S.), Mathematical Films, 155
- Bernal (Prof. J. D.), Vector Maps and the Cyclot Hypothesis, 74; The Social Function of Science (Review), 262; Structure of Proteins, 663; I. Frankuchen and D. Riley, X-Rays and the Cyclot Hypothesis, 897
- Bernkopf (H.), [I. J. Kliger and], Antibiotic Immunization, 80; Cultivation of Rabies Virus in the Developing Chick Embryo, 899
- Bersin (Dr. T.), *Kurses Lehrbuch der Enzymologie* (Review), 138
- Bertman (G. C. L.), Arctic and Antarctic Seals and Sealing, 125
- Bertrand (G.), Quantity of Zinc in Sea Water, 39; and L. Silberstein, Boron Content of Soil, 1039
- Beardka (A.), Antidiphtheric Serotherapy by the Cutaneous Route, 257
- Bett (A. T.), [Dr. J. S. Huxley, C. S. Webb and], Temporary Poikilothermy in Birds, 683
- Bethe (A. A.), Energy Production in Stars, 904
- Bethe (Prof. H. A.), F. Hoyle and Prof. R. Peierls, Interpretation of Beta-Disintegration Data, 200
- Bett (W.), Medicine in the Renaissance, 864; Jubilee of Johns Hopkins Hospital, 907
- Beyer (Dr. M.), awarded the Hanagring prize of the Vienna Academy of Sciences, 298
- Bhabha (Dr. H. J.), The Fundamental Length introduced by the Theory of the Mesotron (Meson), 276
- Bhagvat (Miss K.), [R. Hill and], Cytochrome Oxidase in Flowering Plants, 726
- Bhatnagar (Prof. S. S.), Magnetic Evidence regarding the state of Manganese in Glasses, 599
- Bidder (Dr. G. P.), elected president of the Marine Biological Association, 1063
- Bilham (E. G.), The Weather in Great Britain during 1938, 106
- Binnie (W. J. E.), and H. J. F. Gourley, The Gorge Dam, Hong Kong, 824
- Birch (F.), and D. Baneroff, Effect of Pressure on the Rigidity of Rocks, 769
- Birkhoff (Prof. G. D.), Intuition, Reason and Faith in Science, 60
- Bishop (Prof. M.), Pascal: the Life of Genius (Review), 454
- Bjerger (Dr. T.), K. J. Brostrom and Dr. J. Koch, Decay Curves of Uranium and Thorium Fission Products, 794
- Blagow (A. H.), Ida Luyten and Annie M. Hartsma, Early Flowering of Dutch Irises (2), 488
- Blackburn (Dr. J. M.), The Psychology of Society (Review), 618
- Blacker (Dr. C. P.), [D. V. Glass and], Population and Fertility, 632
- Blackett (Prof. P. M. S.), appointed Scott lecturer in Cambridge University for 1939-40, 306; Cosmic Rays (Kelvin lecture), 816; The Mesotron: the New Unstable Cosmic Ray Particle (Bruce-Prellar address), 1087
- Blair (Dr. G. W. Scott), and Miss F. M. V. Coppen, Differential Threshold for Viscosity, 164
- Blanch (Lloyd E.), Vocational Rehabilitation of the Physically Disabled, 371
- Bland (Prof. J. R.), [Prof. W. F. Kern and], Solid Mensuration, with Proofs (Review), 424
- Bledialoe (Lord), Institution of a silver medal for encouragement in native agriculture, 889
- Bloch (Dr. O.), Photography in Science and Industry (May lecture of the Institute of Metals), 817
- Blundell (G. E.), [obituary article], 886
- Blyth (F. G. H.), and W. T. Marshall, Fractures of Reversed Fault Type produced in Concrete by Torsion, 120
- Bodanaky (Dr. M.), Introduction to Physiological Chemistry. Fourth edition (Review), 1048; and Prof. Marion Fry, Laboratory Manual of Physiological Chemistry. Fourth edition (Review), 1048
- Bodenheimer (Prof. F. S.), Problems of Animal Ecology (Review), 411
- Bodenstem (D.), Imaginal Differentiation Inaugurated by Oxygen in *Drosophila* pupae, 533
- Boedyn (K. B.), and J. A. Verbunt, New Dermatophyte Fungi, 168
- Bohr (Prof. N.), Reactions of Atomic Nuclei, 215; Natural Philosophy and Human Cultures, 268; Disintegration of Heavy Nuclei, 330
- Bolam (Sir Robert), [obituary article], 885
- Bolliger (A.), and A. L. Carrodus, Changes in and around the Pouch in *Trichosurus vulpecula*, 89
- Bolton (E. R.), [obituary article], 507
- Bonacina (L. O. W.), Exhibition of Scottish Art, 87
- Bond (O. J.), Recollections of Student Life and Later Days, 934
- Bond (J.), and R. M. de Schauensee, Bird Fauna of a Rocky Island, 249
- Bonner (Dr. T. W.), Formation of Helium of Mass 3 in an Excited State, 681
- Bonnot (P.), G. H. Clark and S. R. Hatton, Census of Californian Sea-Lions, 249
- Borisiak (Prof. A.), Prof. M. W. Pavlova (Marie Pavlov), 401
- Borley (J. O.), [death], 56; [obituary article], 323
- Born (Prof. Max), Cause, Purpose and Economy of Natural Laws, 357
- Bose (Dr. N. K.), River Physics Laboratories of Europe and America, 825
- Boston (D. W.), Sound-Film Recording, 608
- Boswell (Prof. P. G. H.), retirement of; work of, 57; appointed emeritus professor of the Imperial College of Science and Technology, 198; elected an honorary member of the French Association, 1018
- Bottoher (F. K.), Nicotins and Bees, 299
- Böttger (W.), [O. J. van Nieuwenburg, F. Feigl, A. S. Komarovskiy, N. Strafford and], Tables of Reagents for Inorganic Analysis (Review), 414
- Bounhiol (J. J.), Control of Metamorphosis in Lepidoptera, 771
- Bourne (G.), [Dr. S. Zuckerman, A. Palmer and], Changes in the Water-content of Organs and Tissues as a Result of Stimulation by Oestradiol, 521
- Bowden (F. P.), and L. Leben, Sliding Friction and the Contact Between Surfaces, 567
- Bowden (Dr. S. T.), The Phase Rule and Phase Reactions: Theoretical and Practical (Review), 835
- Bowen (Dr. A. R.), [Prof. A. W. Naah and], The Principles and Practice of Lubrication. Second edition (Review), 580
- Bowen (Dr. I. S.), and Dr. B. Edlén, Forbidden Lines of Fe VII in the Spectrum of Nova RR Pictoris (1925), 374
- Bowie (Dr. W.), awarded the Bowie medal of the American Geophysical Union, 1019
- Bowley (Prof. A. L.), elected an honorary fellow of Trinity College, Cambridge, 888
- Bowman (F.), Introduction to Bessel Functions (Review), 356
- Boyce (Prof. J. S.), Forest Pathology (Review), 413
- Boys (Sir Charles Vernon), awarded the Elliot Crosson gold medal of the Franklin Institute, 818

- Braarud (Dr. T.), Microspores in Diatoms, 899
 Bradford (Dr. S. C.), Documentary Photography and Research, 393
 Bradley (Dr. A. J.), Structure of Meteorites, 518
 Bradley (J. N.), awarded the Herbert Jackson prize of the L.M.S. Ry. Co., 555
 Bragg (Sir William), Combination Tones in Sound and Light, 542; elected a foreign associate of the U.S. National Academy of Sciences, 888; presented with the John J. Carty medal, etc., of the U.S. National Academy of Sciences, 888
 Bragg (Prof. W. L.), Patterson Diagrams in Crystal Analysis, 73; Crystallography, 85; X-Ray Optics, 125; A New Type of 'X-Ray Microscope', 678; elected president of the Institute of Physics, 892
 Brammell (Dr. A.), Transfusion in Petrogenesis, 649
 Brandt (H.), and W. Schummele, Researches on Vitamin C during Athletic Effort, 257
 Branham (J. R.), and M. Shepherd, Analysis of Ethylene Oxide-Carbon Dioxide Mixtures, 729
 Brasseur (M.), and A. de Rassenfosse, Structure of the SnCl_4 -Group, 332; and L. Pauling, Crystal Structure of Ammonium Cadmium Chloride, 481
 Braumholtz (H. J.), Gold Pendant from Ancient Columbia, 767
 Braunstein (Prof. A. E.), The Enzyme System of Transamination, its Mode of Action and Biological Significance, 609
 Bray (F.), Light. Second edition (Review), 318
 Bray (R.), [death], 56; [obituary article], 367
 Brennecke (E.), and others. W. Bottger, Editor. Translated by Prof. R. E. Cisper, Newer Methods of Volumetric Chemical Analysis (Review), 498
 Bressay (Sir Charles), Roads and Traffic, 71; Bigger London or Better London, 235
 Bretscher (Dr. E.), [Dr. N. Feather and], Atomic Numbers of the so-called Transuranic Elements, 516; and L. G. Cook, Transmutations of Uranium and Thorium Nuclei by Neutrons, 559
 Breuil (Abbé), Early Man in the Somme Valley, France, 1016
 Bridge (I. C.), awarded the Wakeham prize of the Institution of Naval Architects, 113
 Bridges (Dr. C. B.), [death], 150; [obituary article], 191
 Brierley (Prof. W. B.), The Botany of Crop Plants (Review), 617
 Brightman (R.), Science in the Modern World (Review), 262
 Briner (E.), [B. Suss and], Absorption by Benzoic Aldehyde in the Violet and the Near Ultra-violet, 257
 Brink (R. A.), and D. O. Cooper, Partial Self-incompatibility in *Medicago sativa*, 89
 Bristow (J. R.), [Dr. E. T. S. Appleyard, Dr. H. London and], Variation of Field Penetration with Temperature in a Superconductor, 433
 Britton (K.), Communication: a Philosophical Study of Language (Review), 959
 Brodhelt (S.), [Prof. The Svedberg and], Splitting of Protein Molecules by Ultra-violet Light and α -Rays, 938
 Bronowski (Dr. J.), appointed lecturer (Grade B) in Hull University College, 1037
 Brunsted (J. N.), Foundation and Formulation of the Thermodynamic Laws, 215
 Brooks (C. F.), Hurricanes into New England, 646
 Brooks (Prof. F. T.), elected an honorary member of the French Association, 1018
 Brostrom (K. J.), [Dr. T. Bjerge, Dr. J. Koch and], Decay Curves of Uranium and Thorium Fission Products, 794
 Brown (A. G.), [M. B. Crane and], Sterility in Plums, 903; Sterility in the Gage and Desert Plums, 946

- Pneumococcus: Infection, Immunity to Experimental, with an Artificial Antigen, Dr. W. F. Goebel, 77; Capsular Polysaccharides, Sulphonamide Drugs and, Dr. M. Stacey and Miss E. Schluchterer, 724
- Poikilothermy, Temporary, in Birds, Dr. J. S. Huxley, O. S. Webb and A. T. Best, 683
- Poisons, Mode of Operation of, [1839], 950
- Polar: Aurora and Night-Sky Light, Prof. H. H. Plaskett, 82; Exploration, 536
- Polyomyelitis, Vitamin C and, A. B. Sabin, 1028
- Polished Surfaces, Grease-free, Preparation of, Dr. I. W. Wark, 1024
- Polonium, Atomic Number of, Spectroscopic Determination of the, H. Hutubei, Mlle. Y. Cauchois and Mme. S. Oteole, 88
- Polymerization of Liquids by Irradiation with Neutrons and other Rays, Prof. F. L. Hopwood and J. T. Phillips, 640
- Polypi of the Mediterranean, [1839], 444
- Polyploid Types, Synthesis of, by Hybridisation, M. Skalinská, 300
- Polyploidy, Induction of, by Pulp and Disintegrating Tissues from *Colchicum* sp., Prof. D. Kostoff, 287
- Polysaccharides, Determination of, Uronic Groups in, Prof. A. G. Norman, 284
- Polythionic Acids, Formation of, Mechanism of, H. Stamm and H. Winter, 988
- Pontifical Academy of Sciences, Prof. A. Conway appointed a member of the, 198
- Pope Pius XI and his Scientific Interests, Dr. T. Greenwood, 274
- Poplars: Cultivated, Dr. R. Melville (Review), 832; The Black, and their Hybrids cultivated in Britain, G. S. Canadale and others (Review), 832
- Population: Distribution of, The Census and the, 310; and Fertility, D. V. Glass and Dr. C. P. Blacker, 632; Problems in Relation to Refugees, 1041
- Portugal, Geology of, [1839], 128
- Positivism: Logical, An Examination of, Dr. J. R. Weinberg (Review), 782; Logical, The Claims of, Dr. T. Greenwood (Review), 782
- Post Office, Col. A. S. Angwin appointed Engineer-in-Chief of the, 677
- Potash-Soda Despers, Lamellar Structure of, S. H. Chao and Dr. W. H. Taylor, 1024
- Potassium: Deuteride, Spectrum of, S. Imanishi, 165; Dihydrogen Phosphate, Anomaly of the Specific Heat of, at the Upper Curie Point, W. Bantle and P. Scherrer, 980; Ions, Permeability of Corpuscles and Muscle Cells to, Dr. L. Hahn, Prof. G. Hevey and O. Rebbe, 1021
- Potato: Problems, Dr. S. Linné, 12; The, in its Early Home and its Introduction into Europe, Dr. R. N.

- Salaman (Masters lectures, 1936), 12; Metabolism and the Blight Fungus, late Prof. P. A. Murphy, 820; Tubers, Diseased, Colouring Matter in the Yellow Spots on, L. Schmid and R. Lang, 1039
 Pre-Crag Implements, J. Reid Moir, 151
 Prehistoric Fire-Dog, A., 552
 Pre-Roman: Sites in Britain, Excavations on, 673; Archaeology in Shropshire, 1059
 Preventive Medicine, appointment of a committee on problems of, 892
 Primitin, Structure of, Synthesis of 5:6-Dihydroxy-flavone and the, W. Baker, 900
 Printed Page and the Public Platform, 237
 Prism, Liquid-filled, An Improved, F. J. Hargreaves, 481
 Probability: Inverse, Frequency Interpretation in Dr. W. E. Deming, 202; Frequency Interpretations in, Dr. H. Jeffreys, 242; Dr. Norman Campbell, 601
 Progesterone: Inactivation of, in the Organism, Prof. B. Zondek, 282; Hypopadias and Non-descent of the Testes caused in Rats by, Dr. H. Burrows, 858
 Pronephric Duct, Formation of, R. J. O'Connor, 81
 Propagation of Plants, Prof. M. G. Kains and L. M. McQueen (Review), 180
 Prospect, Retrospect and, Sir Richard Gregory, Bt., 1
 Protein: Genuine and Hydrolysed Ultra-violet Absorption of, F. Haeurwitz and T. Astrup, 118; Multilayers, Deposition of, R. B. Dean, O. Gatty and E. Stenhagen, 721; Solutions, 'Intraglobular' Reaction, in, D. L. Talmud, 762; Stability as revealed by Ultracentrifugal Analysis, Dr. H. A. Lundgren, 896; Molecules, Splitting of, by Ultra-violet Light and α -Rays, Prof. The Svedberg and S. Brohult, 938
 Proteins: Structure of, Dr. I. Langmuir, 34; Chemistry of the, Dr. Dorothy Jordan Lloyd and Agnes Shore. Second edition (Review), 222; Structure of, Dr. W. T. Astbury and Miss Florence O. Bell; Dr. I. Langmuir, 280; Globular, the Structure of the, Dr. Dorothy Wrinch, 482; 'Intraglobular' Reactions and the Cyclol Structure of, N. Gralén and Prof. The Svedberg, 619; and Viruses, H. Moriyama and S. Ohashi, 528; Structure of, Prof. J. D. Bernal, 663; Absorption Spectra of, E. Holiday, 895
 Protoplasm and its Derivatives, Submicroscopic Morphology of, S. H. Clarke, 965
 Prussian Academy of Sciences, Prof. T. Vahlen appointed president and Prof. H. Scheel director of the, 718
 Psychical: Experiences: Evidence of Purpose, Zoe Richmond; Foreknowledge, H. F. Saltmarsh; Ghosts and Apparitions, W. H. Salter; Hypnosis: its Meaning and Practice, E. Cuddon (Review), 223; Phenomena, Science and, G. N. M. Tyrrell (Review), 223; Research, Academie (Review), 223
 Psychologie expérimentale in Italie, la (Ecole de Milan), Dr. A. Manoil (Review), 353
 Psychology: in Everyday Life, Dr. W. C. Varnum (Review) 427; Factor Analysis in, Prof. Godfrey Thomson and others, 611; Social, Prof. D. Katz and Prof. R. L. Schanck (Review), 618; Experimental, Prof. R. S. Woodworth; Dr. R. H. Thouless (Review), 1047
 Ptolemy's Catalogue of Stars, [1839], 773
 Public Analysts and other Analytical Chemists, Society of, election of officers, 403
 Pyrometry, Art of, 1017
 Pyruvic Acid: Dehydrogenation and Adenylic Acid Phosphorylation, Coupling between, Prof. A. Lipmann, 281; Oxidation System, Flavin Component of the, Dr. F. Lipmann, 436
 Qualitative: Analysis by Spot Tests: Inorganic and Organic Applications, Prof. F. Feigl. Translated by Dr. Janet W. Matthews (Review), 95; Analyse mit Hilfe von Tüpfelreaktionen: Theoretische Grundlagen, Praktische Ausführung und Anwendung, Dr. F. Feigl. Dritte Auflage (Review), 581
 Quantum: Mechanics, The Elements of, Dr. S. Dushman (Review), 8; Theory, The 'Failure' of, at Short Ranges and High Energies, Sir Arthur Eddington, 432
 Quaternions, Matrices of, and the Representation of Eddington's E -number, Dr. W. H. McCrea, 950
 Quartz: Family Minerals: A Handbook for the Mineral Collector, H. C. Duke, F. L. Fleener and B. H. Wilson (Review), 415; 'Acidity' of, Dr. G. Van Praagh, 1068
 Quakett Microscopical Club, election of officers, 469
 Qumey Granite, Halum Ratios of the, N. B. Keevil, 82
 Quinme, Action of, on Skeletal Muscle, A. M. Harvey, 819
 Rabbit Chew the Cud? Does the, Dr. H. Madsen, 981; E. L. Taylor, 982
 Rabies: Sulphanilamides and, R. Kirk, 77; Virus, Cultivation of, in the Developing Chick Embryo, J. J. Kligler and H. Bernkopf, 899
 Racial Fallacies (Review), 137
 Radioactivity: A Manual of, Drs. G. Hevesy and F. A. Paneth. Second edition. Translated by R. W. Lawson (Review), 416; New and Old (Review), 416
 Radiobarytes from Teplitz and Carlsbad, H. Haberlandt, 215
 Radiobromine, R. E. Siday, 681
 Radio: Waves, Scattering of, in Polar Regions, Prof. E. V. Appleton and R. Naismith, 243; -Elements formed in Uranium and Thorium Irradiated with Neutrons, Mme. I. Curie and P. Savitch, 389; -Telemeter and its importance to Aviation, R. W. Knight, 716; Fields, Measurement of, at Ultra-short Waves, F. M. Colebrook and A. O. Gordon-Smith, 769; Soundings in Australian Seas, R. Bureau, M. Douguet and P. Wehrli, 1038; Manganese, Radiations from, J. V. Dunworth, 1065
 Radium: Beam Therapy Research, 1934-1937, Report on, Constance A. P. Wood, L. G. Grimmett, T. A. Green and others, 9; Medical Uses of, 9; Trust and Radium Commission, National, Ninth Annual Reports of the, 1937-1938, including a Statistical Report, 9; Storage of, in War Time, G. F. Stebbing, 644; and (Radium + Beryllium), Very Penetrating Radiation from, Apparent Existence of a, Dr. M. E. Nahmias, Prof. F. L. Hopwood, Dr. T. E. Banks, W. H. Rann and L. G. Grimmett, 1065
 Ram?, What Happens to the, Dr. B. A. Keen, 153
Ranunculus Ficaria, Sexual Reproduction of, C. R. Metcalfe, 383
 Rat: Fleas in Plymouth, R. B. Mayfield, 248; Typhus Virus, Modification of Pathogenic Activity of Two Strains of, maintained by Passage Through White Mice, J. Laigret and R. Durand, 573
Rattus, Distribution of, R. A. Littleford, 1070
 Rattlesnake Venom, Proteins of, Dr. B. N. Ghosh and S. S. De, 380
 Ray Society, election of officers, 555
 Rayleigh Waves, Anomalous Dispersion of, K. Sezawa and K. Kanai, 481
 Rayonnements: Étude pratique des, solaire, atmosphérique et terrestre (méthodes et résultats), Dr. C. Mauram (Review), 744
 Reading University, impending retirement of Prof. F. J. Cole, 38; Dr. C. H. O'Donoghue appointed professor of zoology in, 610
 Recoil Atoms, Range of, Absorption Method for Determining the, Dr. E. E. Widdowson and Dr. S. J. Gregg, 760
 Red: Auroral Lines on September 14-16, Prof. O. Stormer, 117; Deer: A Herd of, a study in Animal Behaviour, Dr. F. F. Darling (Review), 453; The Ways of the (Review), 453
 Reduvius, The 'Fossula Spongiosa' in, N. O. E. Miller, 477
 Refugee Problem: The Report of a Survey, Sir John Hope Simpson (Review), 1041

Retrospect and Prospect

THE public announcement of my retirement from the editorship of *NATURE* was made only a few days before my departure for the United States to deliver the Elihu Root Lecture at the Carnegie Institution of Washington on December 8, and to give a few other addresses at universities, as well as at the Richmond meeting of the American Association, on social and international aspects of science. Before leaving England, it was not possible for me to thank more than a few of my personal and other friends for their kind messages, but to them, and to all who have helped me with contributions and advice during the forty-five years of my association with *NATURE*, first as assistant editor to Sir Norman Lockyer, and later as editor, I welcome the opportunity now given me of expressing my very grateful appreciation of their interest and aid.

Throughout its existence, *NATURE* has had the active support of leading workers in scientific fields in many parts of the world. The aim has always been to record results of research of wide interest or particular importance wherever it has been carried out, and to present authoritative thought and opinion upon progressive scientific developments and their influence. In the early years of the journal, there was little recognition of the practical services which science can render to industry, or of the place which it should occupy in a modern State. Appeals for endowment of scientific research were perversely described as implying the search of scientific workers themselves for endowment in privileged positions rather than

as a means of promoting intellectual and industrial progress. Much still remains to be done before our statesmen and industrial leaders are fully aware of the power which science can give to the community, both socially and materially, yet the general principle that expenditure on research is a profitable investment may be said to have been conceded.

Forty-five years ago, the annual grants of the British Government for scientific investigation and related subjects, as shown in the Civil Estimates, were about £45,000. At the present time, they amount to nearly £2,000,000, of which the Department of Scientific and Industrial Research administers about £700,000. Less than one quarter of the net expenditure of the Department represents, however, grants for purposes directly or indirectly connected with industry; and the actual annual economies introduced into industries as the result of research have a financial value many times greater than the amounts expended upon them. On the most generous estimate, the grants for direct and indirect support of scientific research in Great Britain, including those expended in departments of armed forces, represent only one tenth of one per cent of the national income. While, therefore, it is gratifying to be able to record that the policy of State endowment of scientific research consistently advocated in *NATURE* has been accepted, industrial and social conditions are now changing so rapidly that a much bolder and broader financial scheme will have to be undertaken if the advancing front of

knowledge is to be made available for wise planning and efficient action in times of peace or of war.

Even, however, when adequate provision has been made for scientific research in biological as well as physical fields, whether purely with the object of increasing natural knowledge or for the purpose of industrial development, scientific workers will neglect their special responsibilities as citizens if they are indifferent to the social consequences of their discoveries. To the enlightened public, science signifies the disinterested pursuit of truth by patient observation, critical inquiry, unprejudiced examination of evidence and convincing judgment; but there are still many people who associate it with the conversion of pleasant natural scenes into industrial slums and with clouds of poison gas and other barbarous means of destroying man and his noblest works. It is the duty of scientific workers on one hand to do nothing which would shake the confidence of the community in the principles for which they stand, and on the other to take every opportunity to absolve themselves of responsibility for the prostitution of the gifts with which they endow the human race. It would be a betrayal of the scientific movement if those who represent it failed to play an active part in solving the social problems which their contributions to natural knowledge have created.

It is with such social and international relationships of science that *NATURE* has been largely

concerned during the past twenty years or so; and the recent formation of the new Division of the British Association, as well as the steps taken by the American Association and similar organizations of scientific workers to make their promotion a common cause, represent the beginning of an international movement which may save the world from the disasters now threatening it.

The correspondence columns of *NATURE* have become an international clearing-house of contributions to natural knowledge; and in this field the standard of value is independent of race or nationality or any other measure than originality and scientific worth. Liberty of thought and action are essential for creative scientific work; and progress is impossible when restrictions are placed upon them.

These principles of scientific freedom have been won through generations of struggle with Church and State, and when science neglects to assert them as fundamental conditions of creative work it will commit suicide. The policy of *NATURE* is to establish these rights not only in the interests of scientific workers themselves but also in those of the whole community. My particular mission has been to make men of science conscious of their power and influence in shaping civilized life, and I am happy to know that my successors will continue to proclaim this message as an inspiring intellectual stimulus and a means of promoting the welfare and the brotherhood of the human race.

R. A. GREGORY.

Science for Africa

An African Survey:

A Study of Problems arising in Africa south of the Sahara. By Lord Hailey. (Issued by the Committee of the African Research Survey under the auspices of the Royal Institute of International Affairs.) Pp. xxviii+1838. (London, New York and Toronto: Oxford University Press, 1938.) 21s. net.

FOLLOWING an appeal for a comprehensive survey of Africa and its problems made by General Smuts in his Rhodes Memorial Lecture in 1929, an authoritative committee was formed to give effect to his proposal. Thanks to the generosity and vision of the Carnegie Corporation of New York, funds were made available, and Lord Hailey agreed to undertake the task on his retirement from the governorship of the United Provinces

in India. Five years intensive work has produced a comparative study of the countries, peoples and their indigenous institutions and the influence of the different European Colonial Powers on the development of both in connexion with the exploitation of the natural resources of the whole of the mainland of Africa lying south of the Sahara, with the exception of the Anglo-Egyptian Sudan, the Italian possessions and Liberia. The survey therefore covers an area in which a Dominion of the British Commonwealth, Great Britain, France, Belgium and Portugal "are engaged in a common task, though in some respects with widely different methods of approach".

"The sole object for undertaking the Survey", says Lord Hailey, "was the hope that it might prove of some service to the Powers which have possession of territories in Africa, and of some

benefit to the African people". Understatement and humility could go no further.

In reality, the survey was conceived on a grand scale and has been compiled with imaginative insight and rare judgment. It takes into account every important aspect of the African scene. It is no mere compilation of facts, but a study in breadth and depth enriched by the intuitive and persevering genius of the master mind responsible for its direction and shape and the actual material it contains. To quote its author, "it is not limited to a discussion of the state of our knowledge regarding the problems which are involved in the development of Africa; it attempts also to describe the physical and social background out of which these problems have arisen and to analyse the factors which . . . must determine their solution". Where there are gaps, and they are not obvious, they must be attributed, not to the author and his collaborators, but to those administrations in Africa which, either deliberately or through lack of system, have not made available to the public essential information concerning their activities and problems.

The survey will commend itself to scientific workers because of its freedom from dogmatism, bias, cant or censoriousness. It will make a special appeal to those who have imbibed the spirit of the 'scientific humanism' which has been conjured up by our post-War perplexities. Some years ago, Mr. H. G. Wells expressed the opinion that the only duty of science was exact statement; its only service, truth. We have added to these the responsibility for attempting to ensure that the results of science shall be properly applied. Lord Hailey's great work satisfies all three criteria. This is his approach: "Africa presents itself as a living laboratory, in which the reward of study may prove to be not merely the satisfaction of an intellectual impulse, but an effective addition to the welfare of a people. A scientific approach to the questions of African development demands the study of problems of a social nature equally with those involving the application of the physical sciences. . . . No one question can be studied in isolation. There is close interdependence among all the essential problems of Africa".

The point needs no emphasis that Africa is undergoing a transformation rather than a development along evolutionary lines. Its impact with Western civilization has been so sudden and in many territories so catastrophic that the social and economic institutions which the different tribes have evolved through the centuries have in every case been seriously undermined. Administrations and Christian missions, often from the highest motives, have compelled changes in African social customs and habits, the results of which have

been demoralization rather than the regeneration of the peoples it was hoped to benefit. We have interfered with their marriage customs, their methods of cultivation, their systems of land tenure, their tribal methods of combating disease, their ideas of crime and punishment. In fact, we have attempted to impose on them by decree an entirely new set of values without making adequate provision for the education services which would enable them to understand and appreciate the changes forced on them.

It is now more generally appreciated by the European peoples with colonial possessions that a closer study of the social institutions of the subject races, with the object of attuning our systems of administration to what is valuable in Africa itself, will make the task of development easier and not necessarily slower. The view taken in this survey is that the social conceptions and practices of Africans are the result of a natural process of accommodation to their economic and physical environment. Their social conceptions do not necessarily indicate, what certain subjective investigators would have us believe, that there is any intrinsic difference of character or mental capacity between them and other peoples. A great deal more research is needed on the educability of the African before we can dogmatize on his inherent mental inferiority to the average European or Asiatic.

Take another assumption. The belief was widely held until recently that the relative low density of population in Africa was due to native customs, inter-tribal warfare and the ravages of the slave-trade. In the light of the researches of Orr, Keeble and others on the problems of nutrition it would now seem more probable, however, that the comparatively small population of Africa can be attributed to mineral deficiencies of the soil and other physical characteristics, which militate against the maintenance of dense populations as well as increase their susceptibility, due to malnutrition, to a variety of diseases. If this be the case—and it is certainly a more satisfactory explanation than any other which has been put forward—and if Africa is to be made capable of maintaining a large settled population, remedies must be found. These must be sought for by a more intensive investigation by African Governments of the interrelated problems of anthropology, agriculture, animal husbandry, water supply and health.

Lord Hailey emphasizes other points in connexion with population. In the last hundred years, the estimates given of the population of Africa have varied from 28,000,000 to 205,000,000, based on various methods of computation. Present-day experts give the population as lying between 138,100,000 and 163,300,000, "a fact which affords

an indication of the value which scientific opinion attaches to the systems of enumeration now in use". The discrepancy is so great that it is obviously impossible to state with any assumption of truth whether the population is declining, stationary or increasing. It is just as obvious that statements made with regard to the effect of certain customs on birth-rate and mortality, or the effect of migration of labourers to the mines and other large centres of gainful occupation on population, lack the validity which could be attached to them were accurate vital statistics available.

Students of African problems will find the chapters on political and social objectives, systems of government, law and justice, and native administration a mine of information. There is no other publication where these matters have been dealt with so comprehensively or with such complete objectivity. The problem inherent in the application of the British system of indirect rule to territories where there is a large and powerful white minority, as in Southern Rhodesia, or a small, semi-aristocratic and extremely vocal white settler community, as in Kenya, is clearly outlined. We are shown, too, how the task of French administrators has been none too simple in applying the logic of their own policy of 'Frenchification' to tribes at various stages of development. French critics of British colonial policy assert that while our interest in colonial issues is genuine and well-informed, our policy is characterized by its deficiency in definition of objective and of the method of approach to our problems. They regard our policy as "a series of improvisations which depend for success not on a logical outlook, but on the exercise of a traditional skill in accommodating principles to circumstances". It is interesting to note that the French are now in the process, at least in some of their territories, of reconciling their expedients to their logic. Nevertheless, there is one matter in which the French and the Belgians appear to have been more successful than the British. So far, we have kept too many minor administrative posts for highly-paid British personnel. We have neither been successful in training Africans, nor in recruiting a type of British subordinate official, for routine duties. The consequence is that "British officers appear to be unduly occupied with routine work", due largely to the lack of any clear policy as to the extent or manner of the employment of educated Africans in the administrative or technical services.

The chapters on law and justice, land and agriculture and animal husbandry are all illustrative of the effects of European conceptions and practices upon peoples with entirely different sets of values based on fundamental differences of outlook and

environment. This has resulted in a good deal of confusion, a great deal of friction and the loss of much that was valuable in African customary practice. On all three subjects, Lord Hailey pleads for considerably more research. If native customary law is to adjust itself to meet the needs of advancing society, students of jurisprudence must make a comprehensive study of African law and justice and attempt to evolve a system of law which will combine the best elements of African with those conceptions of European law which are calculated to evoke the greatest measure of agreement from the Africans themselves. Again, the question of legal titles to land is intimately connected with the methods of agriculture of different tribes, their attitude to domestic stock and their migratory customs. We still know too little to dogmatize on any of these subjects. Our interference with the method of shifting cultivation practised by many tribes led, for example, to pressure on the soil in fixed areas, with the result that the necessary period of regeneration was curtailed and the vegetal cover destroyed, the precursor to soil erosion.

In his penultimate chapter, on "The Future of African Studies", Lord Hailey pleads for the creation of two British bodies, the first, an official body charged with the central directions of research, the second, a voluntary bureau of information. The need for the first is due to the lack of direction in certain branches of research work and inevitable duplication of effort owing to the variety of authorities dealing with African problems. Lord Hailey gives full praise for the research work being done in the different African territories, by the tropical research stations, the Imperial Bureaux and the workers commissioned by the special committees of the Economic Advisory Council of the Cabinet, but suggests that a large fund should be created, preferably in the form of a non-lapsing grant-in-aid, under the administration of a committee of the Privy Council or the Economic Advisory Council, whose duty it would be to devise, in association with the appropriate scientific authorities, "the measures for making the most profitable use of the agencies concerned in any one branch of study, be it anthropology, medicine, or agriculture, and for maintaining the necessary contact between them and the agencies concerned with kindred branches of work". Such a committee, he thinks, would be effective in creating a greater interest in, and securing a larger measure of co-operation of, the universities in the solution of African problems, as well as a greater measure of co-operation between Great Britain and other colonial Powers.

Lord Hailey considers that the furtherance of research is the most important contribution Great Britain has to make to Africa at this critical stage

in its development. Unless I mistake him, he is of opinion that money devoted to research must be regarded as in the nature of a capital investment, more important than capital invested in railways and other public utility undertakings. "Errors now made for lack of knowledge which a well-considered [and generous] scheme of special study might supply may well create situations which the future can rectify only at the cost of great effort and much human distress". Every year which passes threatens to rob the effort of investigators of its value, "since conditions are likely to develop which make it progressively more difficult to apply the results of investigation and experiment".

As regards the second and voluntary body, Lord Hailey suggests that a means is required for making information concerning Africa more readily available. The present sources of information are very scattered, difficult of access and there is also difficulty in obtaining readily all the information required by those who take an interest in the economic or scientific aspects of African development.

The Bureau which he envisages would act as a source of information on practically every aspect of activity in Africa, a convenient body to maintain close contact with institutions and voluntary organizations in Great Britain and other countries interested in Africa, and to provide guidance to those who seek to pursue a special study in any subject of interest in Africa. It would publish periodically a survey of contributions made to knowledge of the continent, and generally act as a clearing-house of information and form a common meeting-ground where personal contact could be established between those who desired to improve their knowledge of African affairs.

Enough has been said, it is hoped, to indicate the remarkable quality of this eagerly awaited publication. There is no important problem in connexion with Africa to which new interest has not been given. It is the most brilliantly suggestive and stimulating contribution to the welfare of the peoples of Africa and those who will benefit by the development of that continent that it has been my privilege to read. A. G. CHURCH.

An Anthology of Anthropology

Anthologia Anthropologica:

The Native Races of Africa and Madagascar. A Copious Selection of Passages for the Study of Social Anthropology from the Manuscript Note-books of Sir James George Frazer. Arranged and edited from the MSS. by Robert Angus Downie. Pp. xii+578+10 plates. (London: Percy Lund, Humphries and Co., Ltd., 1938.) 35s. net.

SIR JAMES FRAZER'S method of exposition, not only in "The Golden Bough", but also in all his anthropological works, reveals both the widest reading and the meticulous care of the scholarly mind in exact quotation, or full paraphrase. This is based on a practice, which he has followed now for more than fifty years, of transcribing in his note-books the exact words of any and every authority he has consulted, when it has provided material bearing on his work. Much of this extracted material by now is familiar to his readers through his laudable habit of quotation; but there is still a considerable residue, upon which he has not drawn; and of this quite a considerable proportion comes from authors whose works are now rare, inaccessible, or forgotten. In order that this valuable collection of facts—for the extracts almost invariably are factual—may not be lost, Mr. Downie, under the supervision of Sir James, has made an anthology of the more significant and interesting passages, with

bibliographical details, which he has arranged in geographical order with the view of publication in a number of volumes. The first, dealing with the native races of Africa and Madagascar, is now issued. Volumes dealing with other parts of the world (Australia, Asia, Indonesia, etc.) are to follow in due course. Sir James contributes a foreword, in which he explains the purpose of the volumes as a storehouse of valuable information from authors whose work might otherwise be lost or forgotten.

The African material here presented is arranged in seven books, each covering a part of the continent—South, East, West and so forth. Some of the material is drawn from manuscript sources communicated personally to Sir James by the authors, as for example, Prof. C. G. Seligman on his now famous investigations among the Dinka and Shilluk of the Upper Nile, and the Hon. C. K. Dundas on the peoples of Mount Elgon. Broadly speaking, authors from whom Sir James has already quoted freely, or who do not antedate the twentieth century are omitted, except where they are needed to fill what would otherwise be a gap in information, owing to recent discovery. The advantage is obvious. The facts as given here, for the most part, cannot be impeached as being in any way influenced by anthropological theory, which, as is well known, has been profoundly influenced for more than forty years by the views of Sir James on the development of the human mind.

and of social and religious institutions, customs and beliefs. Thus there are no quotations from J. Roscoe's works on the natives of Uganda and related peoples. Not only has Sir James made a liberal use of Roscoe's work in his own books, but also this work was carried out in close consultation with him throughout. On the other hand, such books as H. Dale and E. W. Smith on the Ba-Ila, or C. W. Hobley's work in East Africa, are well represented, though published since the Great War, as providing evidence not otherwise available.

Detailed criticism of such a volume as this is perhaps not desired, nor is it readily feasible. Certain general reflections present themselves. Criticism may be directed against a collection of this kind on the ground that this or that item is omitted. Here the reason has been explained in part above; but it must also be remembered that an anthology is not a source-book. Its selective character must be allowed; but when the anthologist has a profound knowledge of the sources such as belongs to Sir James, criticism of his choice is a work of supererogation.

A more serious criticism attacks the value of collections of fact as such. This is a criticism of the comparative method in general, now somewhat in disfavour. It is contended that this method of study detaches the facts from their context, and further, in the hands of certain of its

exponents has tended to be uncritical of its sources. The latter is a defect of the individual critical apparatus and tends to correct itself in the view of the judicious. The gravity of the former charge, however, must depend on the way in which the facts are used. Obviously, in comparative study the whole cultural context cannot be incorporated in the text of an argument; the correct use of a fact depends not on the mode of its statement in argument, but on the extent to which its user has appreciated its place in its cultural environment. Further, the purpose of the inquiry must be taken into account. The end of anthropology is the study of man as such. The inquiries to which Sir James Frazer has devoted his whole life are directed to the elucidation of the course of evolution of the human mind, not of the minds of particular groups of men. However valuable and essential the intensive study of cultural and social groups may be, especially at a time like the present when the backward races are changing with extreme rapidity, anthropology, as a science, cannot rest in the study of the particular, but must pass to the universal, if it is to vindicate its title to be a science at all.

In conclusion, it must be mentioned that this first volume of "*Anthologia Anthropologica*" has been produced in sumptuous manner, and the editing has been done both judiciously and with extreme care.

Science and the Chemical Industry

British Chemical Industry :

its Rise and Development. By Sir Gilbert T. Morgan and Dr. D. Pratt. Pp. xii + 387 + 32 plates. (London : Edward Arnold and Co., 1938.) 21s. net.

THE story of chemical industry is the story of man's attempts to convert the raw materials of Nature into something more useful to himself, not by mere mechanical means, as weapons were fashioned from flints, but by transforming them into something entirely different, as, by the action of fire, limestone is changed to quicklime, or a mixture of sand and soda into glass. Some of the industries involving chemical change are of considerable antiquity, including those producing iron, gunpowder, soap, glass and pottery and the extraction of dyes from vegetable materials.

It is to the great outburst of scientific activity during the nineteenth century, following on the pioneering work of those old masters of chemistry, Priestley, Cavendish, Black, Lavoisier, Dalton and others, that modern chemical industry owes its existence. The researches of these men, by putting

chemistry on a sound theoretical basis, established scientific law where formerly there was but a rough empiricism. During the nineteenth century, chemical knowledge and understanding expanded at a great rate, and not only were the changes which matter can undergo unravelled, but also the mineral and vegetable kingdoms were diligently explored, and many new and unsuspected kinds of matter were discovered. If necessity is the mother of invention, surely discovery is the father. The application of these discoveries to arts and manufactures followed, as time went on, with less and less delay until, in the twentieth century the process occurs with bewildering rapidity.

To-day, although it may not be obvious to the 'man in the street', we live in a chemical age. Superficially it may be a mechanical age, but the immense strides in the design of all kinds of machinery have been made possible only by the work of the chemists who have discovered the metals and alloys essential for their manufacture and functioning. Chemistry so pervades all branches of human activity that it is indeed difficult to distinguish, as Sir Gilbert Morgan and

Dr. Pratt point out in the book under notice, which industries should be included in the category of chemical, and which should be omitted. With reluctance they must have decided to leave out the great iron and steel industry from their survey, and also the bleaching, dyeing and finishing industries which, although not producing chemical products, are predominantly chemical in that their operations use vast quantities of chemicals and are controlled by chemists. The authors have, however, given us a most entertaining and enlightening survey of many of the most important chemical industries of Great Britain.

The book is written by chemists for chemists; that is to say, the authors' first aim is to make sure that the chemical changes underlying every process are clearly explained. Nevertheless, successful manufacture in a competitive world depends on the design of the most suitable plant for the necessary operations, and accordingly the book contains a large number of admirable diagrams and illustrations of plant and lay-out. It must be admitted, however, that a photograph of a piece of chemical plant gives as little information about how it works as does one of a modern stream-lined locomotive, and has even less æsthetic appeal. The feature of the book which distinguishes it from others of its kind is the authoritative nature of the matter it contains. The authors have been fortunate, or sufficiently persuasive, to get all the important chapters in the book reviewed and amplified by recognized authorities; it may be taken, therefore, that there are few misstatements, and that, for the more modern industrial developments, as much has been revealed of manufacturing detail as is possible at the present time.

From a descriptive point of view, there is a good deal in favour of classifying the chemical industries according to the raw materials from which they start—salt, coal, cellulose, petroleum and so on. This classification, which has been adopted in this book, immediately distinguishes those industries depending on native supplies from those which have to import their raw material. That the opening chapter should deal with the salt industries is a happy choice, since this leads to descriptions of the Le Blanc and ammonia-soda processes for sodium carbonate. The setting up of the Le Blanc process in Great Britain appears, historically speaking, to have established Britain as a great manufacturing country for heavy chemicals, and some of the greatest names in industrial chemistry are associated with its development and that of its offshoots—such names as Gamble, Crossfield, Tennant, Gossage, Chance, Claus, Deacon and Weldon. The manufacture of soda involved that of immense quantities of sulphuric acid, hydrochloric acid, chlorine, bleaching powder, caustic

soda, and so on. Advances in scientific knowledge, particularly the coming of the electrolytic process for caustic soda and chlorine, provided the opportunity for a rival process, the ammonia-soda process, which starts with salt, ammonia and carbon dioxide instead of salt, limestone and sulphuric acid, to displace the Le Blanc process, which has now become obsolete. In a similar way, the contact process for sulphuric acid is gradually displacing the old lead chamber process; and since the publication of this book it has been announced that a new vanadium catalyst which cannot be poisoned has been put into the most recent plant for the contact process.

It is impossible in a short notice to say a tithe of what might be said of the romance of the rise of the chemical industry: of the spectacular increase in the production of metallic aluminium, and more recently of magnesium; of the intricacies of the isolation of the metals of the platinum group and their present-day key position; of the dyestuff industry, its rise, recession and rejuvenation in Great Britain, and the recent British discovery of the extraordinarily stable 'Monastral' (phthalocyanine) pigments, one of which is used effectively for the cover of the book; of the discovery of new drugs, including the vitamins, some of which are now being manufactured in Great Britain; of the coming of chemistry into the petroleum industry and the use of catalytic processes for improving fuels; of the utilization of the gases of the atmosphere, nitrogen for ammonia and nitric acid, argon, neon, and even krypton and xenon for electrical lamps. We cannot omit to mention the chemical processes which have given us new textile fibres, viscose and cellulose acetate, now manufactured all over the world; the importance of chemistry in agriculture; and finally chemical warfare.

What is the conclusion of the whole matter? Britain's prosperity is based on her industries, and the whole world is becoming industrialized. Progress in industry has long passed the empirical stage and is dependent on the application of science—chemistry, physics, biology—in its highest forms. It is imperative that we have a succession of men of the highest type to staff our industries, thoroughly equipped scientifically, with abundant opportunities for research. The big industries of Great Britain are providing the research opportunities; auxiliary to them are the research associations and such establishments as the National Physical Laboratory and the Chemical Research Laboratory. It is for the universities to supply the trained men for industry whilst retaining within their own walls persons whose gifts are for teaching or for the pursuit of fundamental knowledge. There is some danger that the demands of industry may denude the universities to an alarming extent.

Background to Modern Science

Ten Lectures at Cambridge arranged by the History of Science Committee, 1936, by F. M. Cornford, Sir W. Dampier, Lord Rutherford, W. L. Bragg, F. W. Aston, Sir A. S. Eddington, J. A. Ryle, G. H. F. Nuttall, R. C. Punnett, J. B. S. Haldane. Edited by Joseph Needham and Walter Pagel. (Cambridge Library of Modern Science.) Pp. xii+248. (Cambridge: At the University Press, 1938.) 7s. 6d. net.

THE ten lectures which make up the present volume were delivered in Cambridge during 1936, under the auspices of the then newly formed History of Science Committee, and it is not surprising to learn from the preface that they were attended by crowded and enthusiastic audiences. A glance at the list of authors will show that the Committee was fortunate in being able to enlist the services of a most distinguished team of lecturers, and as the volume itself shows, it was equally fortunate in being able to secure the manuscripts of the lectures in a form suitable for publication.

Apart from introductory lectures on Greek natural philosophy and on the period stretching from Aristotle to Galileo, the remainder of the volume consists of accounts of the progress, during the past forty years, of some of the more active branches of science. Radioactivity, crystal physics, atomic theory, astronomy, pathology, parasitology, evolution theory and genetics have been selected as representing what the dust cover describes as "the cutting edge of human scientific activity". To praise the work of the distinguished authors would be both superfluous and impertinent. Within the very brief space at his disposal—some twenty-four pages—each author has succeeded in giving a vivid, personal, and authoritative 'eye-witness's account' of the progress on his own section of the scientific front. Perhaps some future volume in this excellent library will give us a co-ordinated account of the campaign as a whole.

J. A. O.

The Atlas of To-day and To-morrow

By Alexander Radó. Pp. ix+198. (London: Victor Gollancz, Ltd., 1938.) 10s. 6d. net.

AS, with the advance of science, the world shrinks, human geography grows in importance. Scarcely a generation passes but new States are created or the boundaries of old ones are revised. The present volume is admirable in scope and execution. Its aim is not to dwell upon the more or less static geographical features which find their place in the usual type of atlas, but to provide a cartographic record of that bewildering mass of political and economic problems which have such an important bearing upon the future of mankind.

A more accurate title would be "The Atlas of Yesterday and To-day". Starting from 1875 the authors picture the progressive division of the world by the great powers, the building up of colonial empires, the struggle for world markets and the control of communications, concluding with a brief summary of significant differences in religion, race, nationality and forms of government. The statistical

tables are numerous, concise and instructive, but the reader is left to discover for himself which figures are well grounded and which, at best, can only be rough estimates. In the next edition, to which we may look forward confidently, the use of a comma both as comma and as decimal point (for example, in Table 4) should be avoided, and a serious error throughout the first column of figures in Table 7 should be corrected.

Library Guide for the Chemist

By Prof. Byron A. Soule. (International Chemical Series.) Pp. xiii+302. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 15s.

THERE are published every twelve months about fifteen hundred books, forty thousand articles and 20,000 patents of chemical interest; this flood is increasing at the rate of 6 per cent per annum. The chemist, whether he be research worker or engaged in industry, must be in touch with some portion of this literature if he is to avoid repeating work which has been done elsewhere, whilst there are many others who seek to locate chemical information beyond the purely obvious. The research student gets some kind of training in the use of a chemical library, but it is not always easy to know where to look; moreover, critical judgment as to the quality of the work consulted is an important element for success. It is valuable therefore to have a book entirely devoted to acting as a guide to this enormous literature. That before us is well done, and though of trans-Atlantic origin it will be equally serviceable in a British or European laboratory. A corollary of such work is the existence of really good libraries. Chemists are strangely lacking in a proper sense of co-operative effort and it is a stigma that the library of the Chemical Society, which is still the best in the world, is still inadequately housed and supported.

The Elements of Quantum Mechanics

By Dr. Saul Dushman. Pp. xiii+462. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 25s. net.

DR. DUSHMAN'S admirable book is the outcome of a series of lectures on quantum mechanics delivered by him at the Ohio State University. They were addressed to students who had not received "any intensive training in mathematics beyond calculus". This being so, the development of the various theses is somewhat leisurely but, from the pedagogic point of view, is all the better on that account. The author has selected his topics for discussion with discretion and presents them most skilfully. He deals in turn with the Schrödinger equation, potential barriers, the linear harmonic oscillator, the rigid rotator, the hydrogen and helium atoms, the hydrogen molecule, valence bonds, and the theory of radiation.

The treatment is as elementary as may be; the exposition is remarkably clear, and the book may be warmly commended as an introduction to more advanced treatises.

A. F.

Cancer: Radiological Treatment and Research

THE radiological policy of the Medical Research Council immediately after the Great War was determined by its acceptance from the Ministry of Munitions in 1919 of about two and a half grams of radium element for the purposes of experimental and clinical research. Since then the Council has systematically helped the advance of radiology, especially in its relation to cancer, and from 1922 onwards, with only one omission, it has published yearly reports from research centres in the "Medical Uses of Radium" series. The current issue for 1937* has just been published and maintains in every way the traditions of these publications. A larger section each year is devoted to pure experimental research. One of the chief values of this publication is that it gives a summary of the results of radium treatment of cancer in various parts of the body. The results are given as survival rates, and in many cases the data extend back over a period of ten years or more.

About the same time another valuable contribution, the "Report on Radium Beam Therapy Research", also under the aegis of the Council, has been published†. This report relates in detail the way in which a clinical investigation into the value of large radium units (five grams of radium element) was carried out. The research was begun in 1934 with one five-gram unit, and another similar unit was available in 1936. At the outset, it was decided to limit the research to cases of cancer of the mouth, pharynx and larynx, the reasons for this choice being that they are accessible to direct examination, and that adequate surgery is in many cases difficult and mutilating.

It is impossible here to refer to the many features which give the impression of work admirably planned and no less admirably carried out; there is scarcely a question that comes to the mind that is not answered in the text. It is a welcome sign in the radiological outlook to find a paragraph such as the following:

"It is already noteworthy that doses as large as 8,000 r have failed to sterilize some growths, whereas 4,000 r has been successful in others. It would appear that there are many factors other than dosage which have a profound influence on the response of cancer to radiation."

Turning from radiological research and treatment of cancer to the policy that is to guide its development in the future, two publications call

for comment; one is the "Annual Report of the Radium Commission, 1937-1938"*, the other the text of a Cancer Bill introduced into the House of Commons on November 30 by the Minister of Health, Mr. Walter Elliot. The Bill is the result of the efforts made in the last ten years by those actively concerned in the radiological treatment of cancer. Whether it be an individual or a group or an organizing body, like the Council and Commission already mentioned, or a co-ordinated effort by the British Empire Cancer Campaign and King Edward's Hospital Fund, the result is the sum total of these efforts, and it is to show that radiological methods are of great value in the diagnosis and treatment of cancer. A national policy to ensure more facilities for cancer treatment is overdue, but none the less welcome. The main provision of the Cancer Bill is to establish a service under which, in every part of the country, modern facilities for diagnosis and treatment of cancer will be available. The Bill places an obligation on the major local authorities to consult with the Radium Commission and bodies representing voluntary hospitals and the local medical profession, and to make arrangements for securing the necessary facilities. The Bill provides for an Exchequer grant towards the cost of the new service. When the service is in full operation, the additional expenditure will amount to about £800,000 per annum for England and Wales, and £100,000 for Scotland.

A clause of the Bill provides for "loans to be made to the National Radium Trust for the purchase of additional quantities of radium. Provision is also made enabling money to be lent to the Trust under the section for the purchase of other radioactive substances and apparatus and appliances required for radiotherapeutic treatment. It is proposed that the moneys to be advanced to the Trust, not exceeding £500,000 in all, shall be repayable to the Minister with interest by way of annuities spread over appropriate periods".

Only brief reference can be made to the annual report of the Radium Commission, which includes a statistical report. The outstanding feature of the report is the information upon the use of the bigger radium units, made possible by the provision of another 10 grams of radium. Units ranging from 1 to 3 grams of radium element are in use at no fewer than seven of the national centres throughout Great Britain.

The Government purchase is going to give

* Medical Research Council. Special Report Series, No. 222: Medical Uses of Radium; Summary of Reports from Research Centres for 1937. Pp. 48+2 plates. (London: H.M. Stationery Office, 1938.) 1s. net.

† Medical Research Council. Special Report Series, No. 221: Report on Radium Beam Therapy Research, 1934-1937. By Constance A. P. Wood, L. G. Grimmett, T. A. Green and others. Pp. 77+23 plates. (London: H.M. Stationery Office, 1938.) 4s. net.

* Ninth Annual Reports of the National Radium Trust and Radium Commission, 1937-1938, including a Statistical Report. (Ond. 5953.) Pp. 63. (London: H.M. Stationery Office, 1938.) 1s. net.

Great Britain a big interest in radium as a 'possession'. This will inevitably entail continuous technical and chemical work, such as the filling, redistribution and concentration of radium in containers. The National Physical Laboratory has served the country well in physical measurements, but radium services have always been and will remain incomplete until a physical chemistry laboratory becomes part of the national radium and cancer service.

It is very doubtful whether any country of size and population of Great Britain is better supported and staffed in the fight against cancer, and to their credit it should be remembered that the voluntary hospitals have borne the brunt of radiotherapeutic research. It now remains to be seen how successfully individual efforts can be co-ordinated to the common good.

S. RUSS.

Scientific Centenaries in 1939

By Eng.-Capt. Edgar C. Smith, O.B.E., R.N.

ON May 26, 1639, three hundred years ago, in the ancient convent of the Jacobins, in the historic Rue St.-Honoré, Paris, there passed away at the age of seventy-one years the refugee Italian philosopher Tomaso Campanella, one of those inquiring men of unquenchable spirit, who by their determination to destroy "those errors which had become venerable by antiquity" paved the way for the free exercise of thought and investigation which is one of the treasures of the world to-day. Born at the little town of Stillo, Calabria, on September 5, 1568, he was a contemporary of Kepler and Galileo, and like the latter he incurred the hostility of the Church, although a member of it. Owing to his political activities, he was kept in confinement in Naples by the Spanish Government for more than a quarter of a century, but he was able to write several books, among which was "An Apology for Galileo". He was nearly sixty years of age when set free, but even then was kept under close observation, and in 1634, when sixty-five, he escaped from Rome to Marseilles. In France he was befriended by Louis XIII and Richelieu, and was given lodgings in the convent of the Jacobins in Paris.

The year 1639 also witnessed, not the birth or death of a famous astronomer, but the epoch-making astronomical observation of a transit of Venus, by the young Lancashire clergyman Jeremiah Horrocks. On Sunday, November 24, 1639, in between his religious duties, Horrocks had the intense gratification of witnessing, as he had expected and laboured for, the passage of the planet across the sun's disk. His friend Crabtree at Broughton, near Manchester, through Horrocks, in the late afternoon of that Sunday, also caught a glimpse of the same spectacle. "Thus did two young men, cultivating astronomy together in a state of almost complete seclusion in one of the northern counties of England, enjoy the privilege of witnessing a phenomena which human eyes had never before beheld, and which no one was destined

again to see until more than a hundred years had passed away" (Grant). Hundreds of observers watched the transits of 1761 and 1769, and those of 1874 and 1882, and it was through the interest aroused by that of 1874, that a tablet to Horrocks, with an inscription by Dean Stanley, was placed on the memorial to Newton's nephew, John Conduitt, at the west end of Westminster Abbey.

Cambridge had no chair of mathematics when Horrocks was an undergraduate at Emmanuel College, and it was not until 1663 that the Lucasian professorship was founded. The first occupant of the new chair was Barrow, the second was Newton, the third was Whiston and the fourth was Nicolas Saunderson, who died at the age of fifty-seven years on April 19, 1739. Saunderson had held the chair twenty-eight years, having been appointed to succeed Whiston, who in 1710 was deprived of his post owing to his religious opinions. At this time, mathematics at Cambridge may, as Prof. Turner said, have entered a dark century which it is difficult to contemplate, but assuredly Newton had no more devoted disciple than Saunderson. Blind from the age of a year, Saunderson owed his knowledge of mathematics to the patience and generosity of friends, one of whom, Joshua Durn, took him to reside at Cambridge in 1707. Lord Chesterfield, who was at Cambridge in 1712-14, described Saunderson as a professor "who had not the use of his own eyes, but taught others to use theirs".

Contemporaries of Saunderson in Italy, and France, who made contributions to physical science and who also died in 1739, were Eustachio Manfredi (1674-1739), the elder of the two Bolognese mathematicians and hydraulic engineers bearing that surname, and Charles François Du Fay (1698-1739), who repeated and extended Gray's electrical experiments and was the discoverer of two kinds of electricity which he named the *vitreous* and the *resinous*. He also noticed the discharging power of flames. Du Fay had first been a soldier, but

abandoned the army for science and at his death was comptroller of the Jardin des Plantes, in which post he was followed by Buffon. Manfredi was for a number of years astronomer to the Bolognese Institute and was made a foreign member of both the Paris Academy of Sciences and the Royal Society.

Another tercentenary of much interest is that of the birth of Thomas Tompion (1639-1713), the 'Father' of English clockmaking, whose grave is in the nave of Westminster Abbey.

Among the men of science born two hundred years ago was the Scottish natural philosopher John Robison (1739-1805), an interesting figure in many ways. When twenty years of age, as a tutor to the son of an admiral, he was with Wolfe at the landing at Quebec; at twenty-three years of age he assisted in testing at sea John Harrison's chronometers. He lectured on chemistry at Glasgow, held the chair of natural philosophy at Edinburgh, was the first secretary of the Royal Society of Edinburgh and was the intimate of Watt, Black, Hutton, Playfair, Adam Smith and Hume. His son, Sir John Robison, was a founder of the Scottish Society of Arts.

The mathematicians George-Simon Klugel (1739-1812) and Jacques-Antoine-Joseph Cousin (1739-1800) were also born in the same year as Robison. Klugel, a professor at Halle, was the author of a dictionary of mathematics (1803-8), which was added to by some of his countrymen, while Cousin held a chair at the Collège de France for thirty-two years and another at the École Militaire for twenty years. During the French Revolution, he held public offices with success, and though imprisoned at one time, to him fell the task of ordering the use of the new system of weights and measures.

To these names may be added those of Hewson and Townsend. William Hewson (1739-74) was associated as pupil and assistant with both John and William Hunter, and at the age of thirty-one years was awarded the Copley Medal for researches on the lymphatic system in oviparous vertebrates. His promising career was cut short by poisoning from a wound received while dissecting. The Rev. Joseph Townsend (1739-1816), rector of Pewsey, Wiltshire, travelled and studied mineralogy, and in his writings endeavoured to reconcile the Mosaic record with the findings of science. He was a close friend of William Smith and was one of the first honorary members of the Geological Society.

William Smith (1769-1839) was one of three engineers who achieved fame, and passed away a century ago, the others being William Murdock (1754-1839), the right-hand man of Boulton and Watt, and the inventor of gas-lighting, for which he was awarded the Rumford Medal in 1806, and Gaspard-Clair-François-Marie-Riche de Prony

(1755-1839), writer of many scientific and engineering works, engineer-in-chief of the Corps des Ponts et Chaussées and director of the Survey of France. Smith was a contemporary of Telford and Macadam, and like them travelled on his professional duties the length and breadth of Great Britain. His surveys and inspection of canals, drainage works, mines, quarries, embankments and suchlike all yielded him material for his famous geological map of England and Wales published in 1815, "the first attempt," said Von Zittel, "to represent on a large scale the geological relations of any extensive tract of ground in Europe". Smith in his later years fell on hard times, but seven years before his death he was given a Civil List pension of £100 a year. Another English man of science who died in 1839 was Davies Gilbert, who though himself an accomplished mathematician and physicist, furthered the advance of science more by his public activities than by his researches. He was president of the Royal Society from 1827 until 1830 and for a long while sat in Parliament. "He was," wrote Weld, "emphatically the representative of scientific interests in the House of Commons, and contributed by his exertions to carry many very important objects."

When Smith was laying the foundation of his fame, geology as we know it was in its infancy; when he died, geological societies were active in England, Scotland and France, the Geological Survey of Great Britain had been founded, and instead of being the pursuit mainly of a few men of leisure and of independent means, the science could count its students by the hundred. The growth of the science during last century is to some extent reflected by the fact that the year 1839 saw the birth of at least six men who achieved distinction as geologists. Henry Govier Seeley (d. 1909), a link with Sedgwick, and a Lyell medallist, was born on February 18; Arnold von Lessaulx (d. 1886) of Bonn, a pioneer in microscopic petrography, was born on June 14; James Geikie (d. 1915), the holder of the Murchison chair at Edinburgh, was born on August 23; Karl von Zittel (d. 1904) of Munich, the author of the well-known "History of Geology and Palaeontology", was born on September 25; Edmund Mojsisovics von Mojsvár (d. 1907) a pupil of Suess, and vice-director of the Geological Institute of Vienna, was born on October 18, while the French geologist Albert de Lapparent (d. 1908) who served as president of the French Geological Society and as permanent secretary to the Paris Academy of Sciences, was born on December 30, 1839.

Of men famous in other branches of science who also were born a century ago, the list includes the names of Mond, Eliot, Kundt, Gibbs and Thurston, Ludwig Mond (1839-96), the great industrial

chemist, came to England fresh from the laboratories of Kolbe, Bunsen and Kirchhoff, and stayed to build up the famous firm of Brunner, Mond and Co. and to found the Davy Faraday Research Laboratory at the Royal Institution. Sir John Eliot (1839-1908), from St. John's College, Cambridge, went to teach mathematics in India and became the Director-General of the Indian Meteorological Service, benefiting both those ashore and afloat by his study of cyclones. August Kundt (1839-94), the successor of Helmholtz at Berlin, is remembered for his original investigations in sound and light. Josiah Willard Gibbs (1839-1903), of Yale, was Copley medallist in 1901. He was", said Sir William Huggins, "the first to apply the second law of thermodynamics to the discussion of the relation between chemical, electrical and thermal energy". His name will always be associated with the Phase Rule.

In his own particular sphere, none occupied a more prominent place than the American engineer and educationist Robert Henry Thurston (1839-1903). At the Stevens Institute, Hoboken, Thurston organized the first mechanical engineering laboratory in the United States, while at Sibley College, Cornell University, whither he went in 1885, he saw the number of engineering students under him grow from a total of sixty to 900. He was a founder and the first president of the American Society of Mechanical Engineers.

In conclusion, attention may be directed to one or two of the outstanding scientific books published in the year 1839, and one or two events which excited considerable interest, or proved of lasting importance, to the world of science. Among the books were the first volume of Faraday's "Experimental Researches in Electricity" and Darwin's "Journal and Remarks, 1832-36", which appeared as the third volume of Fitz Roy's

"Voyages of the Adventure and Beagle". Of Darwin's work the *Quarterly Review* said, "We find ample materials for deep thinking; we have the vivid description that fills the mind's eye with brighter pictures than painter can present, and the charm arising from the freshness of heart which is thrown over these virgin pages of a 'strong intellectual man, and an acute and deep observer'". Another notable book was Murchison's "The Silurian System", which Sir Archibald Geikie called a "splendid monograph with which it was now possible to carry the vision across a vast series of ages, of which hitherto no definite knowledge existed", and yet another, W. H. Miller's "Treatise on Crystallography".

The year 1839 was also marked by the announcement by the naturalists Theodor Schwann (1810-82) and Matthias Jakob Schleiden (1804-81) that all the higher animals and plants are made up of cells; by the invention by Sir W. R. Grove of his battery experiments with which Schönbein was led to his observations on ozone; by the discovery by Charles Goodyear of his process of the vulcanization of rubber, and by the first trials of the historic pioneer screw-driven vessel *Archimedes*. But nothing excited more enthusiasm in scientific circles than the publication of the account of Daguerre's method of obtaining pictures on metal plates. On January 7, 1839, Arago communicated Daguerre's invention to the Paris Academy of Sciences, and in the summer the French Government purchased the invention, making the inventor an officer of the Legion of Honour and awarding him a pension of 8,000 francs. A fortnight after Arago lectured at the Academy of Sciences, Faraday at the Royal Institution described Fox Talbot's invention of "photogenic drawing". These were both notable steps in the early progress of photography.

Potato Problems*

By Dr. S. Linné, Ethnographical Museum of Sweden, Stockholm

THE native peoples of America were clever botanists, and the culture inherited from the Indians has supplied humanity with numerous cultivated plants of inestimable value; for example, the potato, maize, cacao, tobacco, tomato, etc. The potato is certainly the most important,

along with maize. In four Masters Lectures before the Royal Horticultural Society, Dr. Salaman has presented the latest discoveries and the results of his own investigations and of those of others concerning the potato in ancient and present times in America, and its introduction into Europe.

It is certainly not surprising that this important cultivated plant, and the question as to its origin, have attracted the attention of botanists, but Dr. Salaman is the first scientist to have studied the potato problem not only from an archaeological,

*The Potato in its Early Home and its Introduction into Europe, Masters Lectures, 1936, by Redcliffe N. Salaman (*Journal of the Royal Horticultural Society*, Vol. 62, Pp. 53+46 figs. London, 1937.)

A brief summary in which certain points of view have been revised has since been given in a discourse entitled "The Origin of the Potato and its Influence on Man's Early Settlement in South America," published in the *Proceedings of the Royal Institution of Great Britain* (80, No. 141, pp. 25+9 figs., 1938).

but also from a 'psychological' point of view. By way of introduction he points out that Russian savants conducted several expeditions during 1928-32 and greatly increased our botanical knowledge of the potato, establishing, among other things, that the majority of the thirteen tuber-bearing species of *Solanum* have, from earliest times, been cultivated by the Indians of South America. They have further demonstrated that the potato, numerous wild forms of which exist from Colorado to Chile, but which was only cultivated in South America in pre-Columbian times, developed in two distinct areas. They are the Peruvian and Bolivian plateaux (*Solanum andigenum*) and the Island of Chiloe and neighbouring parts of the Chilean coast (*Solanum tuberosum*). The common domestic potato of Europe, and *S. tuberosum*, are identical, and according to the Russian investigators it then follows that the potato introduced into Europe towards the end of the sixteenth century came from Chile.

Dr. Salaman, however, holds an entirely different opinion, and the evidence presented by him appears to be irrefutable. First of all, the parts of the Chilean coast referred to had not yet been conquered by the Spaniards, for the natives made very stubborn resistance, and it must thus have been rather a difficult task to obtain potatoes there. Even though it may have been possible, the crop would then have been harvested at a very unsuitable time for the potatoes to be set in Europe. Chile is in the southern hemisphere and the potato is harvested in April. Considering the communications at that time, the potatoes would be of no use for planting on their arrival in Europe; and they also would have been stored for some time in the tropics. In the Peruvian and Bolivian highlands with their varying nature, however, it would have been possible to select a more suitable time. The difficulties of transportation would have been considerably simplified if seed had been taken instead of tubers, but this must be considered excluded. The Indians, who taught the Spaniards how to cultivate potatoes, always planted tubers, and still do, and it was European botanists who later became interested in the seeds.

Also, from a botanical point of view, difference between *S. andigenum* and *S. tuberosum* is so small that, according to Dr. Salaman's analyses, it cannot be definitely determined whether the European potato had its origin in one or the other. It is known from the time that the potato was first cultivated in Europe that it set seed freely, which is a characteristic of *S. andigenum*. Seedlings were raised, and new varieties were soon produced. The Indians cultivate about one hundred varieties, and everything indicates that they had a very rich

assortment also in early times. At village fairs in southern Peru, the natives have been seen to offer for sale more than sixty different varieties of potatoes.

As regards the introduction of the potato into Europe, it has hitherto been considered that 1588 was the earliest fixed date. The potato was then cultivated in Italy, having come from Spain. However, thanks to various data in the literature hitherto overlooked, Salaman has succeeded in demonstrating that it was cultivated in the neighbourhood of Seville in 1572, and he considers it likely that it was first introduced at least ten years earlier.

A little later, but quite independent of Spain, the potato made its second entry into Europe, this time into England. However, it did not come from Virginia, as is often stated; for it is not native there and was not introduced there until more than a hundred years later. Salaman is of the opinion that Sir Walter Raleigh should have the credit of being the first to introduce and plant potatoes in England, and that this was in 1586. There is as yet no absolutely conclusive proof of this very momentous event, but apparently the introduction occurred on two occasions, quite independently; in Spain and in England, the potato thence finding its way to the rest of Europe. In both cases, the potato derived its origin from Peru, Bolivia, Ecuador, or Columbia, but scarcely from Chile.

We can obtain a knowledge of the early history of the potato and of its use in America from the chroniclers of the conquest and from the pottery found in pre-Spanish graves on the Peruvian coast. Seeing that the art of writing was unknown in South America, it is the archaeological investigations alone that can throw light upon the history of the country prior to the arrival of the Spaniards. The pottery thus plays a prominent part; for the wonderfully shaped ware of the Peruvian people portrays human beings and animals, weapons and tools, scenes of everyday life, battles and religious ceremonies. The pottery from Chimú, on the northern part of the Peruvian coast, is especially outstanding in virtue of its ever-varying choice of motifs, vivid naturalism combined with a keen eye for artistic effects and unsurpassed technical skill. Five consecutive periods can be distinguished and be dated approximately, from the beginning of our era up to the arrival of the Spaniards and the downfall of Inca in 1533. The Chimú ware is thus also the main source of our knowledge of the use of the potato in prehistoric times and of the religious conceptions attached to it.

The potato was cultivated in the highland valleys and plateaux of the Andes, but for climatic reasons it was not cultivated on the slopes towards

the coast or on the actual coast, that is, in the river valleys, which, separated from each other by stretches of deserts, were the only districts suitable for agriculture, especially for the cultivation of maize. Several types must have been raised at a very early date: *inter alia*, a hybrid form which was rather frost-hardy. It is very probable that, in its native country, the potato has been cultivated for three millenniums.

It is strange that only in the pottery of the coastline do we find reproductions of the potato. This is due to the fact that the highland ware on

YELLOW ANTHROPOMORPHIC POT FROM CHIMBO. FIGURE COMPOSED OF POTATO TUBERS WITH PRONOUNCED 'EYES'. NOTE THE EXCISED NOSE AND EMERGED UPPER LIP. Reproduced by permission of the Council from J. Roy. Hort. Soc., 62 (1937).

the whole has no reproductions of either human beings, animals, or other objects. Thanks to the dry climate—there is practically no rain—and the high nitrate content of the soil, everything that was deposited in the graves on the coast has been preserved. Even in the graves dating from the oldest Chimú culture has there been discovered pottery in the shape of potatoes and chuflo, that is, preserved potatoes. The manner of producing chuflo, freezing, treading on the tubers spread on the ground, with the view of squeezing the water out of them, and drying, is to this day the same as that described by the Spaniards four hundred

years ago, and was undoubtedly the same two thousand years earlier. Probably chuflo is one of the first preserved foodstuffs that ever existed. Not until potatoes were cultivated and this method of preservation introduced could the Peruvian and Bolivian highlands feed a more numerous and permanent population. It is thus impossible to over-rate the importance not only of the potato but also of chuflo for man's conquest of these territories.

One of the theories upon which Salaman founds considerable parts of his historical comments is that the Peruvian coastal population crossed the mountains from the South American primitive forests. This is connected with his opinions as to how man originally took possession of the continent, and here the presence of chuflo in the graves on the Peruvian coast plays a prominent part. Salaman considers that the immigrants were unable to penetrate the Isthmus of Panama on account of its rain-forests and its generally inhospitable nature. In the event of their crossing from Central America to South America in canoes, chuflo, which did not exist in Central America, would not have been found in the graves on the coast. Certainly the woods in the Isthmus of Panama are difficult to penetrate, and I know from my own experience that this is true with reference to Europeans but not as regards the natives. Nor must the fact be forgotten that the whole Isthmus has from ancient times been inhabited by native tribes, and that even they have produced cultures of a high level. Furthermore, the Peruvian coast was undoubtedly populated long before the potato was common food and before the culture flourished from which Salaman has obtained his archaeological proof. This is demonstrated, *inter alia*, by the remains found after the primitive fisher population at Arica and other places.

That "the original settlers reached South America via the great river systems of the Orinoco and the Amazon" is a hypothesis that remains to be proved, and can be accepted only when further reasons have been produced. According to Salaman, these early immigrants found little attraction in the forest and river districts and made their way up the high Andes. The reason for their doing so he considers can be expressed "in the one word fear", which would appear to be rather too simple an explanation, especially as the forests had quite a considerable Indian population which have produced rather highly developed cultures, suited to the conditions, and satisfactory for their existence. We are unable to determine what occurred in a dim and distant past when South America was gradually becoming populated by immigrants from the north. Weaker peoples were elbowed out by stronger ones; migrations and

displacements were continually occurring due to various causes. Undoubtedly, the jungle and rain-forests were not populated very extensively until comparatively late; primitive culture as well as real civilization belonging to the dry territories.

The above-mentioned Chimu vessels with potato motifs have been arranged by Dr. Salaman in certain groups with special reference to the motifs, these groups also being chronologically separated from each other. Those dating from the oldest period are mainly anthropomorphic, that is, having human shapes, but they display tuber-like parts in which the 'eyes' of the potato are represented.

like form, are increasingly suppressed. During the Inca period, finally, there are seen only faint traces of the eyes, the potato-shape, too, having almost vanished.

Dr. Salaman is of the opinion that the mutilation of the nose and lips is a kind of ritual sacrifice. For reasons unknown, he assumes that "for the sake of the potato" the coastal population originally sacrificed human beings, but that later they contented themselves with the mutilation, which was finally replaced by merely removing the upper lip. The Peruvian potato tuber is often blood-red, with very deep eyes surrounded by a brow.

PROTO-CHIMU ANTHROPOMORPHIC POT FROM TRUJILLO. CREAM AND RED. FRONT AND BACK VIEW SHOWING EXTREME MUTILATION OF NOSE AND MOUTH. BACK OF HEAD ORNAMENTED WITH POTATO EYES. Reproduced by the permission of the Council from *J. Roy. Hort. Soc.*, 62 (1937).

The majority portray human beings with mutilated faces; nose and lips have been cut off. The oldest vessels are most severely mutilated; in the later ones the mutilation is often merely indicated, and finally it was limited to the removal of the upper lip.

Later, there appear no mutilations, though the pots maintain their anthropomorphic type, but with tuber-like projections and the stigmata of the potato eye. Gradually the human shape attracts less and less interest and the potato-shape becomes more and more predominant. During the Late Chimu period the realism at last almost disappears: thus also the mutilations, and the tuber-

According to Dr. Salaman's hypothesis, the natives looked upon the eyes as a mouth from which the new buds stood out like teeth. As the potato-spirit had to be given new strength to replace what had been consumed, this would be accomplished by a sacrifice which in some manner was connected with the potato's most important part. Experience had taught the native that the bigger the mouth and the more prominent the teeth, the richer was the crop. By removing the lips and denuding the teeth of the sacrifice, the resemblance to the potato mouth was created, and the potato-spirit could not be mistaken as to what was expected from him.

I regret to say that I can scarcely follow, and still less agree with, these views. We do not know the part played by the potato in the household of the coastal population, nor do we know whether or not chuffo was present in the graves of pilgrims from the mountains. It certainly seems very improbable that the coastal population should have made sacrifices to the potato-spirit operating in the highland districts, with which they had nothing to do but to purchase his products. There are, moreover, numerous vessels portraying mutilated faces which have nothing whatever to do with the potato, and which medical specialists have presumed to represent morbid changes, *inter alia*, syphilis. It would not appear very remarkable that, in their art, which need not always be of a magic character, the natives found reason to express a resemblance between a face deformed by a disease and the potato, which resemblance certainly may be striking.

As a support for his theory, Dr. Salaman has collected a large number of instances of sacrifices and ceremonies of various kinds connected with the setting and harvesting of potatoes from the discovery of South America to the present day. These rites subsist as an echo of ancient times, but they do not prove that the coastal people sacrificed human beings to the potato-spirit, or that the mutilation portrayed by the pots is an expression of a fertility rite.

Dr. Salaman's studies overflow with interesting, personal working theories, which, however, in many cases cannot very well be made to agree with our knowledge of the customs of the South American natives. It is indeed very satisfactory, though in many cases one may feel sceptical of the results, that an important problem is discussed so extensively without considering ordinary archaeological and ethnological methods and with fresh points of view.

News and Views

Sir Richard Gregory, Bart., F.R.S.

A PERIOD of forty-five years is but as a day in the life of a State; it is a large fraction of the life of one man. Yet, as will be seen from the first article in this issue, it represents the period during which Sir Richard Gregory has been associated with *NATURE*; and since 1919 he has governed the policy of the journal, which has become intimately associated with his name. His retirement will come as a shock to many readers, and it will be a loss to all that his great qualities of leadership, matured by long association with the journal, will no longer be directly available to us. In his message to readers of *NATURE*, in the present issue, he has stated in his own inimitable fashion the policy that has ever guided and encouraged his labours for science and for humanity, and there is no need to elaborate them here. They may be summed up in two phrases: a clear recognition of the importance of the reactions of advances in science on the well-being of the community, and intense faithfulness to the ideals of the freedom of learning and its independence of national boundaries, of caste and of creed.

NATURE, probably more than any other periodical of its age and status—it will shortly celebrate the seventieth anniversary of its birthday—has preserved a consistency of outlook which has widened rather than changed fundamentally with the changing years. This is in great measure due to the wisdom and foresight of the two editors, Sir Norman Lockyer and Sir Richard Gregory, who have for so long a period guided its fortunes. Sir Richard, in particular, clearly perceived the increasingly large share which science was bound to take in moulding the social life

of the community, and the corresponding increase in the responsibilities of the man of science towards that community whose fate may, nay, will, be determined by the use, or misuse, of the powers that he puts into its hands. These views have, of late years, been elaborated with increasing force in these columns, and the world at large is deeply indebted to Sir Richard Gregory for the vigour and clarity with which he has expounded them. His retirement from active participation in *NATURE* will, we trust, release him for yet further public work for the advancement of civilization and progressive science.

Sir James Jeans, O.M., F.R.S.

THE appointment by His Majesty the King of Sir James Jeans to the Order of Merit is a well-deserved reward for outstanding work in mathematical physics and astronomy. Jeans's earliest investigations were concerned with the dynamical theory of gases; by the use of generalized co-ordinates, he gave a rigid proof of Maxwell's law of distribution of molecular velocities, and of the theorem of equipartition of energy. He also improved the theory of viscosity and made important contributions to the theory of radiation and of quanta. When a pupil of Sir George Darwin, he had become interested in the difficult problem of the stability of the pear-shaped form of rotating, incompressible, gravitating fluid. Darwin, Poincaré and Liapounoff had discussed this with discordant results. By a masterly piece of analysis, carried to a third-order approximation, Jeans was able to show that this form was unstable. He then turned to the more difficult problem, which is of greater importance for cosmogony, of a rotating mass of compressible fluid, and showed that for a

density greater than a certain critical value, the behaviour is generally similar to that of the incompressible fluid, but that for lower densities equatorial break-up, by ejection of matter from the equator, will occur. These results were applied to the evolution of the solar system, binary stars and spiral nebulae in an essay that was awarded the Adams Prize in 1916. The conception of gravitational instability as a cause of the separation of primitive material was due to Jeans. In his important investigations in stellar dynamics, the methods that he had developed for the kinetic theory of gases were applied to the stars.

In recent years, Jeans has written a number of popular books on astronomy and physics which have had a world-wide circulation and have done much to create an interest in the more recent developments in these branches of science. Jeans served as secretary of the Royal Society from 1919 until 1929, and as president of the Royal Astronomical Society from 1925 until 1927. He received a Royal Medal of the Royal Society in 1919 and the Gold Medal of the Royal Astronomical Society in 1922. He was president of the British Association in 1934, and president of the Indian Science Congress at its jubilee meeting in 1938.

New Year Honours

The following names of men of science and others associated with scientific work also appear in the New Year Honours list: *Baronet*: Hon. Surgeon Commander J. D. Pollock, for benefactions and services to education. *G.C.M.G.*: Lord Hailey, director of the African Research Survey. *G.C.V.O.*: Sir John Reith. *G.B.E.*: Sir Frank Smith, Secretary of the Department of Scientific and Industrial Research, lately secretary of the Royal Society. *K.C.M.G.*: Sir Algernon Aspinall, lately secretary to the West India Committee. *Knights*: The Hon. Walter Gordon Duncan, president of the Royal Agricultural and Horticultural Society, South Australia; Prof. W. W. Jameson, dean and professor of public health, London School of Hygiene and Tropical Medicine; Prof. R. Robinson, Waynflete professor of chemistry in the University of Oxford; Mr. Will Spens, master of Corpus Christi College, Cambridge; Prof. R. G. Stapledon, professor of agricultural botany, University College of Wales, and director of the Welsh Plant Breeding Station, Aberystwyth. *C.B.*: Mr. A. T. A. Dobeon, fisheries secretary, Ministry of Agriculture and Fisheries. *C.M.G.*: Mr. J. N. Oliphant, director of the Imperial Forestry Institute, Oxford. *C.I.E.*: Dr. W. Burns, agricultural expert to the Government of India in the Imperial Council of Agricultural Research Department; Lieut.-Colonel G. Covell, director of the Malaria Survey of India; Mr. A. C. Hiley, chief conservator of forests, Bombay; Mr. H. B. Dunnilliff, chief chemist, Central Revenues Chemical Service, and principal of the Government College, Lahore; Lieut.-Colonel E. W. O'G. Kirwan, professor of ophthalmic surgery, Medical College, Calcutta, Bengal. *G.B.E.*: Mr. W. F. Brown, chief mineral adviser to

the Commissioners of Crown Lands, member of the board of governors of the Imperial Institute and of the Institute's Advisory Council on Minerals; Dr. A. S. Griffith, bacteriologist, Medical Research Council; Mr. R. P. Nicholson, lately secretary of the Royal African Society; Mr. F. C. Starling, assistant secretary and director of the Petroleum Department, Mines Department.

O.B.E.: Prof. W. E. Agar, professor of zoology, University of Melbourne; Dr. H. R. Angell, senior pathologist of plant industry, Council for Scientific and Industrial Research, Commonwealth of Australia; Lieut.-Colonel K. R. Krishnaswami Ayyangar, lately director of the Pasteur Institute of Southern India, Coonoor; Mr. B. E. Frayling, chief inspector of mines, Tanganyika Territory; Mr. P. A. Godwin, director of surveys and lands, Sierra Leone; Mr. D. K. S. Grant, conservator of forests, Tanganyika Territory; Prof. C. J. Hawkes, professor of engineering, King's College, Newcastle, member of the Departmental Committee on the Examination of Engineers in the Mercantile Marine, 1937; Mr. W. F. Higgins, secretary of the National Physical Laboratory, Department of Scientific and Industrial Research; Miss Hilda Matheson, secretary to the African Research Survey; Mr. T. Rowatt, director of the Royal Scottish Museum; Mr. J. E. A. Wolryche-Whitmore, for services to agriculture in Kenya. *M.B.E.*: Mr. D. O. Drummond, deputy conservator of forests, United Provinces, India; Mr. R. T. M. Hayter, assistant director of the School of Tropical Medicine and resident medical officer, Carmichael Hospital, Calcutta, Bengal; Mr. O. H. C. Shelswell, lately personal assistant to the chief conservator of forests, Madras.

Captain B. S. Cohen, O.B.E.

CAPTAIN BERTRAM S. COHEN, who retired from the post of staff engineer in charge of the Post Office Research Station at Dollis Hill, London, at the end of December, has been for forty years improving instruments and developing methods used in telephony. He joined the National Telephone Co. in 1896, the year in which the Post Office bought the long-distance telephone lines throughout the United Kingdom. As early as 1900, when Sir Oliver Lodge demonstrated his hornless loudspeaker before the Institution of Electrical Engineers, Cohen was one of the first to recognize the clearness of the articulation of the device, the faithful reproduction of radio telephony greatly impressing him. In conjunction with G. M. Shepherd, he did excellent work in applying some of Heaviside's work to long-distance transmission over telephone lines. With impressive thoroughness, they evaluated the solutions of the very lengthy and difficult equations, sometimes involving inverse hyperbolic functions, which were continually arising in their experimental work. Cohen contributed a paper to the Physical Society in which he discussed the alterations in the everyday solutions due to the fact that the 'constants', such as the resistance, in some of the differential equations were really variables, and the solutions consisted of terms having

different frequencies. He received the O.B.E. for the excellent work he did in telephony during the Great War. The Institution of Electrical Engineers awarded him the Fahie Premium and an 'extra' premium for two of his papers; he is now president of the Meter and Instrument Section of the Institution. He leaves the Post Office with the good wishes of all his colleagues.

South Africa's 'Men-Apes'

THE chief findings of a report on the teeth of the fossil 'men-apes' of South Africa by Prof. W. K. Gregory and Dr. Milo Hellman of the American Museum of Natural History, New York, which are cited in a communication by them in another column of this issue of NATURE (see p. 25) tend both to confirm, and at the same time to extend, the implication of Dr. Broom's diagnosis of the human affinities of his recently discovered relics of new types of fossil prehomnids. As a result of a personal inspection of the finds, these two authorities, whose judgment carries conclusive weight in view of their experience in the examination of the dentition of fossil apes from the Himalayan tertiary deposits, give it as their considered opinion that "the dentition of the adult forms described by Broom present many transitional or annectant conditions between the pithecioid and human stages". They go on to support and illustrate this pronouncement by reference to details of the dentition of one of these forms, namely *Plesianthropus*. For example, a canine of the female specimen is said to "require but little additional modification to attain the human status". What, however, is of special significance is that Prof. Gregory and his colleague find in the Indian fossil forms transitional stages leading to the almost human premolar of *Plesianthropus*, while another tooth of the South African type takes an intermediate position between *Sivapithecus*, one of the fossil anthropoids from the Siwaliks, and Peking man. A further significant suggestion, based on comparative evidence, is that the general condition of the teeth points to a stage of transition from the frugivorous habits of the ape to the omnivorous habits of man.

Phylogeny and Chronology in the Descent of Man

It may be noted that the conclusions at which Prof. Gregory and Dr. Hellman have arrived in regard to the dentition of the South African fossil men-apes by no means dissipate, but rather intensify, the chronological difficulties which, as has been pointed out previously, arise from these discoveries and from the inferences drawn from them by Dr. Broom. A phylogenetic succession is in process of being established in South Africa which chronologically is at variance with—that is, is later in time than—the chronological position assigned on geological and palaeontological evidence to early types, definitely human in character, found elsewhere, such as, for example, Peking man. In other words, this South African series is too late in date for inclusion in the human phylum, and must belong to an analogous line of development which ultimately dies out.

In this connexion, reference may be made to a communication which has been received from Prof. Franz Weidenreich, of the Cenozoic Research Laboratory, Peiping, who directs attention to the fact that he had already arrived at the conclusion from the *Sinanthropus* findings that the adoption of the upright posture and gait had preceded the decisive changes of brain and dentition; and he goes on to suggest that the parts upon which Dr. Broom relies, especially the lower end of the humerus, are not so strikingly different from those of modern chimpanzees as are the shafts and proportions of the long bones. In regard to the chronological problem in particular, he refers to two communications by himself, one appearing in *Biomorphosis* (1, 1; 1938), and the other presented to the Congress of Anthropological and Ethnological Sciences, Copenhagen (1938), in the course of which the discrepancy between the morphological and the chronological sequences of hominid remains is set out in detail in relation to geographical distribution. The interpretation of the evidence put forward by Prof. Weidenreich in an attempt to reconcile the two series, is that we must not look for a single place of origin in man's evolution, but that there must have been at least four centres in which the line of man has developed independently: south-eastern Asia, giving rise to the Australian type of modern man; eastern Asia, giving rise to the Mongolian; Africa, where Rhodesian man affiliates with the Negro; and Palestine or western Asia, from which the European type originated. He is careful to point out that this polycentric evolution of man does not imply a polygenetic origin.

The Kut Barrage Irrigation Scheme

THE last day of 1938 was notable in the sphere of civil engineering operations by reason of the completion of an important four-year undertaking (begun in December, 1934) which has comprised the construction in Iraq of a barrage, 1,500 ft. long, across the River Tigris, and, as an adjunct, of an irrigation canal, $2\frac{1}{2}$ miles in length and 230 ft. wide, with a head regulator to control the flow of water down the Gharraff River. The object of the Government of Iraq in executing the work is to bring into cultivation extensive areas of land on both sides of the Shatt-el-Gharraff from Kut to Ur, between the Rivers Tigris and Euphrates, on the traditional site of the Garden of Eden. Previously, supplies of water have been available for the Gharraff River only during periods of flood in the Tigris; henceforward, the Kut Barrage will retain the water of the Tigris and cause it to flow at all seasons along the diversion canal into the Gharraff River. The barrage has fifty-six sluice gates, each 20 ft. wide, to control the rate of flow, while a navigation lock will enable river craft to pass the obstruction and maintain the service of boats between Bagdad and Basrah. The formation of the canal involved the excavation of 1,600,000 cubic yards of material and the employment of 3,500 Arabs and Kurds. In addition, 250,000 cubic yards of concrete were placed in the barrage. The regulator at the head of the canal is equipped with seven sluice

gates, each 20 ft. wide, and there is a small navigation lock. The constructional operations were seriously hampered in November 1936 by extensive rains, which produced the highest flood on record on the Tigris for that season of the year, and rose with such unprecedented rapidity that the works were entirely inundated and brought to a standstill. A further difficulty was the extraordinary range of temperature, which varied from freezing point in winter to 125° F. in the shade in summer. The engineers for the undertaking were Messrs. Coode, Wilson, Mitchell and Vaughan-Lee of Westminster, and the contract was entrusted to Messrs. Balfour, Beatty and Co., Ltd., of London.

School of Oriental Studies

THE School of Oriental Studies in the University of London, it is stated in the report of the Governing Body for the academic year 1937-38, will vacate the premises at Vandon House, Westminster, now in temporary occupation, for the new building on the Bloomsbury site of the University, in March 1941. Owing to the inconvenience of present arrangements, removal at the earliest possible date has become imperative. At the moment, not only has the library to be housed in another part of Westminster, away from the academic and administrative work of the School, but also a large part of the collection of Chinese and Far-Eastern books, some 16,000 in number, brought together by the late Sir Reginald F. Johnston, professor of Chinese in the University of London, and presented to the library by his executrix, cannot be utilized and must be kept in store. The work of the School, which covers a wide range, now includes in addition to the study of languages, lectures on the religions of the Orient, Indian art, archaeology, and philosophy, Burmese law, history, and economics, Buddhist law, and Indian social welfare. In the school of languages during the academic year instruction was given in Arabic, Persian, Sanskrit, Malay, Hindustani, Chinese, Japanese, and Burmese, the number of students in each being in the order named; while in the African Department there were students in such little known tongues as Efik, Ibo, Lunyoro, Shona, Tswana, Twi, Yao, Yoruba, and Zande. The extent to which these facilities are appreciated is shown by the fact that there were in 1937-38, 85 full-time students, 94 part-time, 197 occasional, and 73 inter-collegiate students, making 449 in all, an increase of 21 on the numbers of the preceding year. Since the death of Sir Montague Butler, chairman of the governing body, in March last, Lord Harlech, formerly Secretary of State for the Colonies, has accepted that office.

Geological Museum: Recent Acquisition

RECENT additions to the collections of the Geological Museum include a number of specimens of beautifully banded pink rhodochrosite, from Minas Capillitas, Catamarca, Argentina. This mineral, which is the carbonate of zinc, is of a rich pink colour, the specimens being of stalactitic formation. Although previously employed as a semi-precious

stone, its use has hitherto been relatively rare: but rhodochrosite from the same source as the Museum specimens was recently utilized in London under the name of 'Inca Rose', in various Christmas gifts, to form an inlay at the edges of white marble-onyx cigarette boxes, and in similar ornamental work in which malachite or lapis lazuli is frequently used. The mineral was collected by Dr. Franz Mansfeld from an old mine, until recently deserted, situated at an altitude of about 10,000 ft., in the Andes. The Museum has also received as a gift from Mr. T. C. F. Hall a small collection of specimens of alluvial gold from Abyssinia and Korea. The Abyssinian specimens include a sample of gold dust, associated with particles of iron ore, in a feather quill, as brought in by the natives. Other acquisitions include two very fine stalagmitic and stalactitic specimens of melanterite (ferrous sulphate) from Millelose Mine, Warrencar, Derbyshire, presented by Prof. W. G. Fearnside; and a large crystal of corundum or impure ruby some five inches in length and three inches in diameter. A number of specimens of seepages of mineral oil found associated with British coal-seams have also been placed on exhibition.

Articulation of Secondary with University Education

THE United States Office of Education has issued a report, entitled "Some Factors in the Adjustment of College Students", of elaborate investigations of university entrance conditions in relation to the varying needs and capacities of individual students. Seven factors have been studied: articulation of high-school and university subject areas, extra-curricular activities, lapse of time between leaving high school and admission to university, age on admission, high-school marks, aptitude and achievement test results, effect on university students of simultaneously engaging in gainful occupations. It is suggested that university courses be made to fit entering students either by dovetailing them with the high-school courses or "by setting up a few broad, comprehensive courses which challenge the interest and ability of the student" as in the University of Chicago (the humanities, the social sciences, the physical sciences, and the biological sciences). The report concludes with a formulation of the following desiderata: a more comprehensive system of record-keeping in the high-school for use in guidance of students; utilization by universities in admitting or guiding the student of as many items of knowledge concerning him or her as possible and, to this end, the provision by them of facilities for testing and interviewing them; integration of the work of the high school and the university through facilities for students of different levels of general scholastic aptitude; and shepherding of students into particular courses in accordance with their past achievements.

Library Service in the United States

A REPORT on library service, prepared by C. B. Joeckel for the Advisory Committee on Education, has been issued by the U.S. Government Printing Office. The survey indicates that the total library

resources of the United States are great but are unequally distributed among the major geographic regions, the different population groups and the various kinds of library service. In all types of library service the north-east and the far west are in a preferred position, while the southern regions are definitely inferior. Urban population is much better served than rural areas, and the library needs of the scholar and the student are usually better supplied than those of the general reader. Again, more than four fifths of public libraries in the United States have incomes of less than the lowest limit usually defended as efficient and only four per cent have incomes of more than 25,000 dollars, the minimum income for an efficient library unit, according to some investigators. Control over the many types of libraries is dispersed among the Federal, State and local Governments, and between public and private educational authorities. Only a small beginning has been made in the planned integration of the library resources of the nation. The library services of the Federal Government itself are generally excellent, but could be improved and extended at relatively moderate cost; and the report details ways in which the Federal Government could improve the general situation by improving the organization and national services of its own libraries, by assistance in the development of regional library service and by grants-in-aid to libraries.

Mortality Rates in the 'Depressed Areas'

In a report entitled "A Study of the Trend of Mortality Rates in Urban Communities of England and Wales, with Special Reference to 'Depressed Areas'" (*Reps. on Pub. Health and Med. Subjects*, No. 86. London: H.M. Stationery Office. 1s. net), Dr. Lewis-Fanning gives the results of an investigation on the effect of trade depression on the national health. Such investigation must be based upon mortality rates, as complete statistics of sickness rates are not available. Standardized death-rates of all the county boroughs within the depressed areas were calculated, and were compared with the standardized rate of mortality for the whole country and with that of a group of county boroughs in prosperous areas, for the same periods. Dr. Lewis-Fanning's conclusion is that there is no evidence from the trend of mortality rates from all causes of death that the health of the population of the depressed areas of the North and of Wales has been unfavourably affected by the economic depression. Excessive mortality these areas certainly have, both when compared with England and Wales as a whole and with other sections of the country, but this excess is not peculiar to the years of depression; it has been a consistent feature of the depressed areas for at least the past twenty years. It is possible that there are a few exceptions to this general conclusion, and in Merthyr-Tydfil the mortality experience in respect of tuberculosis presents grounds for misgiving, but the evidence as a whole is strong testimony of the success of national and local efforts to mitigate evils of great magnitude.

Rural School Hygiene in France

L. FAURE-MURET (*Thèse de Paris*, No. 276; 1938) states that the organization of rural school hygiene in France is practically dependent upon the local authorities, especially as regards financial support. Much more attention, therefore, is given to the subject of school hygiene in large urban communities than in country districts. At the present day, the rural school in France is very much behind the times as regards progress in hygiene. The buildings are often in a state of decay and without proper sanitary annexes. The health of the school child is not properly cared for, and instruction in the theory of hygiene is quite inadequate. In certain country districts medical inspection scarcely exists, and even when it is provided, the medical man is not properly supplied with what he requires. M. Faure-Muret maintains that school hygiene should assume a far more important place in rural areas than in towns, as the conditions of life in the country, in spite of a certain number of favourable natural conditions, are inferior to those of life in towns. Urgent measures are needed for the benefit of the race.

Garden Plants from Equatorial East Africa

ENGLISH gardens owe much of their present floral beauty to plants of other geographical regions, brought by botanical explorers. It is perhaps rather surprising that the flora of high mountains in equatorial East Africa has as yet made no such contribution to European horticulture. Mr. Patrick M. Syngé has shown, moreover (*J. Roy. Hort. Soc.*, 63, Pt. 10, Oct. 1938) that many plants of this region are also found in the English flora. It is therefore to be expected that the more striking indigenous flowering plants of Ruwenzori, the "Mountains of the Moon", and Mt. Eggon, might prove amenable to cultivation in our more temperate latitudes. Mr. Syngé indicates some of the more promising of these; species of giant *Lobelia*, arborescent *Senecio*, *Heli-chrysum* (everlasting), *Impatiens*, *Hypericum*, *Kniphofia*, and others. Some species, as *Kniphofia Snowdenii*, are already to be found in the catalogues of enterprising nurserymen, and Mr. Syngé's illustrations give potent promise of many other striking plants.

The Physical Society's Annual Exhibition

THE Catalogue of the twenty-ninth Annual Exhibition of Scientific Instruments and Apparatus held at the Imperial College of Science and Technology on January 3, 4 and 5 by the Physical Society covers 241 pages, 187 of which are devoted to trade exhibits, and 37 to research and educational exhibits (1 Lowther Gardens, S.W. 7. 1s. 6d.). The two discourses were delivered in the large lecture theatre, on January 3 by Dr. J. D. Cockcroft on "The Cyclotron", and on January 4 by Mr. C. S. Wright on "Polar Geophysical Research". The number of firms exhibiting is slightly larger than last year, but the research and educational section is somewhat less. In the trade section the name of the firm and the number of the stand are given at the head of each page; and the index gives under each

instrument mentioned the pages on which descriptions of such instruments will be found. Some of the illustrations are not very informative, while others show internal details by cutting away enclosures, and a few give wiring diagrams.

Archaeological Investigations in Turkey

A REPORT of results of the continued excavations of the Neilson Expedition to Turkey of the University of Liverpool on the site at Mersin in Southern Turkey, records the discovery of the remains of a fortified city, of which the architectural structure is remarkable (*The Times*, January 3). The gateway is flanked by towers; and a defensive wall is pierced by a range of narrow windows. Piles of improvised missiles lie at hand. The whole city was destroyed by fire while still in occupation; and the contents of the buildings, which include a palace, are said to be complete, though much burned by fire and broken. These remains were encountered at a depth of twenty feet below those of the Hittite city brought to light by the expedition last year. They are assigned to a date at about 3600 B.C.

Earthquake near Japan

THE U.S. Coast and Geodetic Survey, in co-operation with Science Service and the Jesuit Seismological Association, has made a preliminary determination of the epicentre of the earthquake of November 22, 1938, 1 h. 14.1 m. G.C.T., and finds it to be situated in latitude 37° N., longitude 142° E. This was made possible by reports from the seismological stations at Honolulu, Manila, Zikawei, Victoria, Georgetown, Fordham, Sitka and Philadelphia. This epicentre is under the bed of the ocean to the north-east of the main island of Japan, and is near the epicentres of the shocks of November 5 and 6, which were lat. 38° N., long. 141° E., and lat. 36° N., long. 144° E. respectively.

Earthquake in Belgium

THERE was an earthquake during the evening of December 30, with epicentre in the vicinity of Spixhe, near Spa, which caused the collapse of chimneys and moved furniture but caused no casualties. This recalls the earthquake of June 11, 1938, which probably had an epicentre somewhat to the north-west of the present one, and was felt in England, France, and Germany as well as in Belgium (*NATURE*, 141, 1090; 1938). The other epicentre near the present one was located in the International Seismological Summary as lat. 51° N., long. 6° E., which is to the north-north-east of the Spixhe shock and just inside the borders of Germany. Earthquakes occurred from the German epicentre on January 5, 1926, and January 14, 1928.

Announcements

WE regret to announce the deaths of Mr. Emile Mond, honorary treasurer of the Chemical Society and of the Faraday Society, on January 1, aged seventy-three years; and of Prof. Victor Grégoire, professor of botany in the University of Louvain, on December 12, aged sixty-eight years.

PROF. EJNAR HJERTZSPRUNG, director of the Observatory and professor of astrophysics in the University of Leyden, has been elected *correspondant* of the Section of Astronomy of the Paris Academy of Sciences in succession to the late Dr. W. W. Campbell.

AMONG the recent medal awards of the Royal Horticultural Society are the following: Victoria Medal of Honour to Dr. W. F. Bewley, Mr. H. R. Darlington, Mr. F. G. Preston, and Mr. G. Reuthe; Veitch Memorial Gold Medals to Mr. M. B. Crane and Miss I. Preston.

A CENTRE for aeronautical studies and research has recently been founded at Milan by the Italian Ministry of Aeronautics.

THE University of Porto Alegre, with the support of the Federal Government of Brazil, has decided to erect a hospital including a pathological institute.

THE Cornell University Medical College, New York, has received from the Jane Coffin Childs Fund for Medical Research the sum of 4,500 dollars for experimental investigations of leukaemia with special reference to extra-chromosomal factors. The research will be carried out by Drs. C. L. Opie and J. Furth, of the Department of Pathology.

THE Government Health Service of the Dutch East Indies has instituted an investigation among medical practitioners as to their experience with medicinal plants. This will be carried on at the same time that the Commission on the Commerce of Medicinal Herbs is conducting a botanical and pharmacological analysis and a series of technical experiments in the cultivation of such plants.

THE Hellenic Travellers' Club has arranged a tour on March 18–April 7 to sites of medical interest in Greece. At Epidaurus, Prof. G. E. Gaek will lecture on the cult of *Asclepius*, and visits will also be paid to Cos, where the school of Hippocrates flourished, Cnidos, Pergamos, the home of the school of Galen, Athens and Mycenae. Further information can be had from the Secretary, 3 Albany Courtyard, Piccadilly, W.1.

THE Royal Academy of Sciences of Turin announces that the thirty-first award of the Bressa Foundation Prize will be made during 1941. The prize, of the value of 9,000 lire, will be awarded to the man of science, either Italian or foreign, who, in the opinion of the Academy, shall have made the most notable and useful discovery or produced the most important work during the period 1937–41 in any of the following branches of science: physical and experimental science, natural sciences, pure and applied mathematics, chemistry, physiology, pathology, geology, history, geography and statistics. Authors who wish to have their work considered are invited to send copies, which must be printed, to the secretary of the Academy, Via Maria Vittoria 3, Turin, not later than January 31, 1941. R273

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 29.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Estimation of Vitamin A

EARLY in 1937, the results of biological and spectroscopic tests for the vitamin A content of a specimen of halibut liver oil and of a concentrate prepared from it were published in *NATURE*¹. Ten laboratories participated in this co-operative experiment. It was hoped that by enlisting so many groups of workers the uncertainty of the biological results, due to the error inherent in the biological technique, would be minimized, and that an authoritative pronouncement could be made on the magnitude of the value for the conversion factor relating the results obtained by spectrophotometric and biological methods. As a result, a value of 1,470 was reported for the halibut liver oil, whilst that for the concentrate was lower, lying between 1,000 and 1,200. Spectroscopic control carried out on the materials distributed for the feeding tests indicated a satisfactory degree of stability for the oil, but the concentrate deteriorated during the period occupied in the work by an amount sufficient to account for the lower value.

The value 1,470 then communicated as the conversion factor for the sample of halibut liver oil was a provisional one, since the results had not been subjected to statistical analysis. Since then, the statistical analysis has been completed by Dr. J. O. Irwin, of the London School of Hygiene and Tropical Medicine, who gives the final figure for the conversion factor for this specimen of halibut liver oil as 1,670. This result, therefore, agrees remarkably well with the value 1,600 provisionally adopted by the Second International Conference on Vitamin Standardization (1934).

The experiment did not, however, dispose of discrepant but well-accredited results obtained in the course of independent attempts to redetermine the conversion factor. One very important instance was that of the United States Pharmacopoeia reference cod liver oil, adopted as subsidiary international standard for vitamin A at the 1934 International Conference. The value reported in 1934 for this oil

for $E_{1\text{cm}}^{1\%}$ 328 m μ was 1.44, as determined from the average result of tests by four sets of individual workers, or 1.58 according to Morton and Edisbury (see ref. 2, Table IV, p. 30), who are responsible for the spectrophotometric estimations in the present experiment. The biological potency assigned to the oil at that time was 3,000 I.U. per gm., representing the average of results collected from nine different laboratories by Dr. E. M. Nelson. The individual values ranged from 2,400 to 3,725 I.U. per gm. (ref. 2, p. 38). The conversion factor for this oil at that time was therefore 2,080 or 1,900, according to the value accepted for the contemporary spectrophotometric estimation. Materials tested against this oil have also tended to show high conversion

factors of about 2,000; it seemed essential, therefore, that this oil should be subjected to another co-operative test.

A fresh sample of the oil was kindly contributed by the Committee of Revision of the U.S. Pharmacopoeia, and tests similar to those described for the previous experiment¹ were made. The same precautions were taken to secure uniformity in dilution, and spectroscopic criteria were used to check the stability of the solutions used for the biological experiments. A special dilution of the international β -carotene standard was prepared, as before, by the Department of Biological Standards of the National Institute for Medical Research. The dilution of the U.S.P. reference oil was made by Dr. R. A. Morton and Dr. J. R. Edisbury of the University of Liverpool, who also made all the spectrophotometric tests.

Ten laboratories took part in the biological tests. The stability of the solutions used for the biological tests was satisfactorily maintained throughout.

The biological values obtained by the individual laboratories were submitted for statistical examination to Dr. J. O. Irwin, who reported that they ranged from 1,334 to 3,270 I.U. of vitamin A per gm.; six of the ten values lay between 2,200 and 2,600 I.U. per gm. and the weighted mean was 2,619 I.U. per gm. The mean limits of error per experiment ($P = 0.99$) were 73 to 137 per cent.

The value of $E_{1\text{cm}}^{1\%}$ 328 m μ for the unsaponifiable fraction of this particular sample of the U.S.P. reference oil was 1.44. The conversion factor, as determined in this test, is therefore 1,820.

If the result of this experiment is accepted, and the present biological potency for the U.S.P. oil is taken as 2,619 I.U. per gm. instead of the accepted 3,000 I.U. per gm., it is clear that the biological value of all substances tested against the U.S.P. oil for as long as it has possessed this value should be only 2,619/3,000 of that reported, and the conversion factor for each of such substances should be subject to a similar diminution. Even when this correction is applied, the conversion factor, as in the present case, may still be high.

A calculation has been made by Dr. Irwin which shows that the difference between the logarithms of the conversion factor of 1,670 for the halibut liver oil, and of 1,820 for the U.S.P. oil is 2.1 times the standard error, and that the odds are about 30 to 1 against this result being a chance difference. Before a final decision can be reached it will probably be necessary to carry out a third co-operative experiment when a pure vitamin A ester becomes available. Meanwhile, there seems no other course open than to recommend the continuation of the provisional value 1,600 as the best compromise, and again to await further data.

Those who participated in the work were: A. L. Bacharach and E. Lester Smith, Glaxo Laboratories, Ltd., Greenford; R. G. Booth, British Cod Liver Oil Producers (Hull), Ltd.; W. A. Broom, Messrs. Boots Pure Drug Co., Ltd., Nottingham; H. M. Bruce and K. H. Coward, Pharmaceutical Society, London; A. D. Emmett, R. A. Brown and M. Sturtevant, Messrs. Parke, Davis and Co., Detroit Laboratories (communicated by J. A. Freeman); E. M. Hume, Lister Institute, London; J. O. Irwin, London School of Hygiene and Tropical Medicine; S. K. Kon, National Institute for Research in Dairying, Shinfield; T. Moore, Dunn Nutritional Laboratory, Cambridge; R. A. Morton and J. R. Edisbury, University, Liverpool; S. W. F. Underhill, Messrs. The British Drug Houses, Ltd., London; H. Wilkinson, Messrs. Lever Bros., Ltd., Port Sunlight.

A Rapid Visual Test for Vitamin A Deficiency

THE recovery of vision after blinding by a bright light depends, among other things, on a reformation of visual purple from vitamin A in the blood. Various instruments have been used to test this relationship, but have been severely criticized. In all such work, at least fifteen minutes have been needed for each test, and usually much longer.

A new apparatus has been devised to test vitamin A deficiency rapidly. After looking at a bright light of certain intensity for 30 seconds, the time needed to see a dim light of constant intensity is taken (in distinction to instruments which have complicated means for varying the intensity of the dim light). The range of recovery times is 3-50 seconds, an average test takes less than a minute, and two or three tests are made within five minutes of the subject entering the room. Up to forty persons an hour have been tested.

Treatment with vitamin A of 123 people having more than fifteen seconds recovery time (taken as deficient), showed a response in all cases but three, ending in a recovery time of ten seconds or less (taken as normal). Thirty other cases treated with an A-free oil showed no change on repeated tests.

A normal person beginning at eight seconds placed on an A-deficient diet gradually lengthened in recovery time until a time of twenty-seven seconds was reached. At this point haemeralopia, asialia and other symptoms of A-deficiency were present.

Normal recovery time on this apparatus is considered to be ten seconds or less, and over fifteen seconds is deficient. These somewhat arbitrary times were arrived at in the following way: (1) An early survey of a hundred people was plotted to show the number of cases at each recovery time. The form of this curve is the same with our present total of 1,200 cases. The mode is eight seconds, and there is a pronounced dip at 11 seconds. All values less than eleven seconds were therefore tentatively adopted as normal. (2) Large amounts of vitamin A have no

effect on recovery times already at ten or less; but recovery times at twelve or twenty or more, treated with vitamin A come to values of ten or less, depending on the individual.

In a survey of a thousand university students, 52 per cent were normal (3-10 sec.), 24 per cent border-line (11-15 sec.), and 24 per cent deficient (16 or more) with respect to vitamin A.

From these students, 753 case histories were obtained, and the following are some of the relationships found:

	Normal (per cent)	Border-line (per cent)	Deficient (per cent)
Cold within a month after test	54.5	64	71.5
Night blindness	7	18.	19
Dry skin	7	16	18

A total of 1,200 people have been tested and no relation has been found to sex, age, colour of eyes, wearing of glasses if usually worn, myopia, hypermetropia, astigmatism or fatigue. These and other factors are still being investigated. On the other hand, every deficient case has been found to have had a low intake of vitamin A (where calculated this has ranged from 500 to 2,000 I. U. daily).

Full details of the apparatus, and of these investigations, will be published elsewhere.

Laccase, a Blue Copper-Protein Oxidase from the Latex of *Rhus succedanea*

IN 1883 Yoshida¹ discovered, in the latex of the Japanese lacquer tree (*Rhus vernicifera*), a thermolabile substance which was responsible for the darkening and hardening of the lacquer.

To Bertrand² we owe the first extensive study of this substance which he found in the latex of an Indo-Chinese lacquer tree (*Rhus succedanea*). He described this substance under the name of laccase, and showed it to be an enzyme capable of catalysing the oxidation of different polyphenols such as hydroquinone, pyrogallol and others. He has also shown that the darkening and hardening of latex is due to the catalytic oxidation by this oxidase of natural polyphenols, urushiol and laccol. This important discovery of Bertrand was confirmed and extended by other workers and more recently by Suminokura³ and Brooks⁴.

The laccase for our present study was obtained from the latex of *Rhus succedanea*. For the extraction and purification of the enzyme the latex is treated with acetone, the precipitate is dried, extracted with water and the enzyme is then purified by a method somewhat similar to that used by us for purification of polyphenol oxidase of mushrooms⁵.

The purified enzyme catalyses the oxidation of polyphenols and diamines, the oxidation of *p*-phenylenediamine being twice as fast as that of catechol. Monophenols such as *p*-oresol or tyrosine are not oxidized at all by purified laccase even when tested for ninety minutes. Both crude and partly purified enzymes catalyse the oxidation of ascorbic acid without the addition of a carrier such as catechol.

The purest enzyme preparation obtained has a strong blue colour. It is devoid of haematin, iron and

manganese, and contains 0.154 per cent copper. The colour of laccase solution containing 0.015 mgm. copper per c.c. is of the same intensity as a 7 per cent copper sulphate solution. The colour disappears reversibly on the addition of a very small amount of substrate such as ascorbic acid or hydroquinone. It also disappears on boiling the enzyme or treating it with cyanide and diethyl-dithio-carbamate.

The activities of different preparations are proportional to their copper contents. All this shows that laccase is a copper-protein compound belonging to the same group of enzymes as the polyphenol oxidase of potatoes¹ and of mushrooms². If the polyphenol oxidase of mushrooms containing 0.3 per cent copper is 90–100 per cent pure, the laccase preparation containing 0.154 per cent copper would be 45–50 per cent pure. This laccase preparation, however, contains 55 per cent of a polysaccharide and only 6.45 per cent nitrogen, which corresponds to about 45 per cent protein. Assuming now that the polysaccharide is an impurity not connected with the enzyme and the copper is bound only to the protein, the copper content of the laccase protein would be about 0.34 per cent, which is the same as the copper content of crystalline haemocyanin³. If one allows for the polysaccharide content of our purest preparation, the Q_{01} of pure laccase would appear to be about 40,000 with *p*-phenylenediamine as substrate at 20° C.

The activity of laccase is strongly inhibited by potassium cyanide, hydrogen sulphide, sodium oxide and diethyl-dithio-carbamate but not by carbon monoxide, and this holds true whether catechol, *p*-phenylenediamine or ascorbic acid are used as substrates.

Although laccase belongs to the group of copper-protein enzymes, it differs in the following respects from the polyphenol oxidase of cultivated mushrooms (*Psilocybe campestris*):

(1) Laccase is distinctly blue while polyphenol oxidase is yellowish or colourless.

(2) Laccase oxidizes *p*-phenylenediamine better than catechol, while polyphenol oxidase scarcely attacks it.

(3) Laccase, when pure, does not oxidize *p*-cresol at all, while polyphenol oxidase in this reaction shows a distinct lag period, which, as we have shown, becomes more protracted on gradual purification of this enzyme⁴.

(4) Crude laccase preparation oxidizes ascorbic acid directly; this activity decreases on purification and can partly be restored by the addition of catalytic amount of *p*-phenylenediamine but not of catechol. Polyphenol oxidase, on the other hand, whether crude or pure, oxidizes ascorbic acid only through a carrier like catechol. The Q_{01} of this latter reaction using only 0.02 mgm. catechol is still very large (540,000)⁵.

(5) Laccase is not poisoned by carbon monoxide, while polyphenol oxidase, as we have shown, undergoes a very strong, although light-insensitive, inhibition by carbon monoxide⁶.

(6) The activity of laccase ($Q_{01} = 40,000$) is of the same order of magnitude as that given for potato oxidase¹. Both enzymes show only a twentieth of the activity of the polyphenol oxidase from cultivated mushrooms. This is clearly demonstrated especially when the activities of laccase and mushroom oxidase are estimated in the same way.

It may be mentioned that the purification of polyphenol oxidase from a wild mushroom (*Lactarius vellereus*) gave a yellowish preparation containing

0.2 per cent copper and having Q_{01} of about 250,000 for catechol and of only 1,640 for *p*-phenylenediamine.

The results of this communication, apart from the fact that they reveal the nature and properties of laccase, are interesting in some other respects. They dispose of the criticism of our work on the polyphenol oxidase of mushrooms made by Kubowitz⁷ who, without justification, assumes that the properties of different plant phenol oxidases must be the same as those of the potato oxidase. These results also serve as a warning against generalizations based on an incomplete knowledge of the subject and against the tendency of ascribing to one enzyme the properties of another enzyme in the same class, contrary to all the available evidence.

The Sympathetic Character of the Nucleus Supraopticus

In a recent publication dealing with the question of whether nerve fibre terminals or pituitary cells in the pars nervosa of the pituitary secrete the hormones pitocin and pitressin¹, I quoted Ranson, Kabat and Magoun² as holding the view that the nucleus supraopticus of the hypothalamus was sympathetic in character. I was under the impression that the hypothalamic sympathetic centre, which extends to the chiasm, also included the nucleus supraopticus. On re-reading their work, it was found that a small paragraph had been overlooked in which it is definitely stated that there was no evidence that the nucleus supraopticus was included in this sympathetic centre.

I apologize to these authors for this error and retract the above-mentioned quotation. However, other evidence quoted (Kappers³) indicates that the nucleus supraopticus is sympathetic. Crouch and Elliott⁴ found that sympathetic reactions were regulated by the hypothalamus as a whole; but better responses were obtained from anterior and lateral nuclei. Because of this, I think that the nerve terminals of the hypothalamohypophyseal tract are either adrenergic or cholinergic, as are the terminals of other autonomic fibres, and do not secrete the characteristic nervous hormones.

Heteroauxin Production by Efficient and Inefficient Strains of *Rhizobia*

It has been suggested by Thimann¹, Link, Wilcox and Link², and Link³ that β -indole-acetic acid (heteroauxin) is the agent partially or entirely responsible for the formation of nodules on the roots of leguminous plants. Thimann¹ advances the hypothesis that the root nodule bacteria convert tryptophane into heteroauxin, (a) by stimulating elongation of a lateral root and (b) by arresting root elongation through continued auxin production, resulting in the formation of a nodule. If this condition exists, there may be differences in the rate of formation and in total amounts of heteroauxin derived from tryptophane, between efficient and inefficient strains of *Rhizobia*.^{*} (Efficient: *Rhizobia* which infect the host plant and benefit the latter by the symbiosis; inefficient: *Rhizobia* which infect the host plant but fail to aid in fixing atmospheric nitrogen.) Nodules produced by efficient strains are generally characterized as being large and usually located on the crown of the tap-root, indicating early invasion, while inefficient strains produce very small nodules which are distributed over the secondary root system, indicative of relatively late invasion.

The purpose of these investigations was to determine whether or not early or late invasion could be correlated with rate and amount of production of β -indole-acetic acid. The substrate upon which the *Rhizobia* were grown consisted of mannitol 1.0 per cent, K_2HPO_4 0.05 per cent, $MgSO_4$ 0.02 per cent, $NaCl$ 0.01 per cent, $CaCO_3$ 0.1 per cent, KNO_3 0.05 per cent and tryptophane ('Pfanstiehl') 0.05 per cent. In contrast to Chen's medium⁴, in which yeast extract was the source of nitrogen, the above medium contained inorganic nitrogen. No β -indole-acetic acid could be detected in uninoculated controls. Neither could heteroauxin be detected in ether extracts of cultures inoculated in the basal media (same as above with tryptophane omitted), indicating that the bacteria were unable to synthesize the auxin when potassium nitrate was used as a nitrogen source and mannitol as a carbon source.

The basal medium was sterilized at 15 lb. pressure for 15 minutes and a solution of tryptophane, sterilized by filtration, added aseptically. Preliminary tests in which 'tryptone' ('Bacto') or peptone ('Bacto') plus 'tryptone' was substituted for tryptophane, yielded data similar to those in the accompanying table, with the exception that the uninoculated controls frequently yielded positive tests for heteroauxin. Therefore, the medium cited above was used exclusively.

FINAL CONCENTRATION OF β -INDOLE-ACETIC ACID IN 5 ML. MEDIUM AFTER FOUR WEEKS (AVERAGE OF FOUR EXPERIMENTS).

	Efficient	Inefficient	
<i>Rh. meliloti</i>	1: 75,000	1: 10,000	
<i>Rh. trifolii</i>	1: 42,000 (R)	1: 75,000	
<i>Rh. leguminosarum</i>	1: 42,000	1: 45,000 (R)	
<i>Rh. phaseoli</i>	1: 52,000	1: 42,000 (R)	
<i>B. radiobacter</i>			1: 10,000 (24 hr.)
Controls (uninoculated)	0	0	

(R) indicates cultures which brought about a rapid conversion.

Cultures were incubated at room temperature for four or five weeks. Presence of heteroauxin was first detected by the *Avena* technique, but later a colorimetric method⁵ was employed to test for indole-acetic acid. Cultures were tested three times weekly, during the course of each experiment, by withdrawing aliquots aseptically. Subcultures into litmus milk at periodic intervals failed to reveal any contamination. The strains studied were *Rh. meliloti* cultures

107 (efficient) and 120 (inefficient), *Rh. trifolii* 202 (inefficient) and 209 (efficient), *Rh. leguminosarum* 317 (efficient) and 333 (inefficient) and *Rh. phaseoli* 403 (inefficient) and 414 (efficient)*.

B. radiobacter, commonly found in the root nodules of the Leguminosae, transformed tryptophane into β -indole-acetic acid at a more rapid rate than the *Rhizobia*, yet this organism does not produce nodules on the roots of legumes.

From the data cited, there is no apparent correlation between the rate and amount of indole-acetic acid derived from tryptophane and the ability to fix atmospheric nitrogen by the strains of *Rhizobia* studied. In fact, there is a tendency for the inefficient to produce auxin more rapidly than the efficient strains. Chen⁴ reports that ineffective strains in most of his experiments produced less growth substance than effective ones. He used *Rh. trifolii* only, and our data substantiate his in this respect but not when *Rhizobia* of other cross inoculation groups were studied. The fact that *B. radiobacter* likewise produces heteroauxin further complicates any interpretation of the data. What significance, if any, can be attached to the production of β -indole-acetic acid by *Rhizobia* in the light of the behaviour of *B. radiobacter*?

Fossil Man-Apes of South Africa

By invitation from Dr. Robert Broom, of the Transvaal Museum, Pretoria, and from Prof. Raymond A. Dart, of the Medical School, University of the Witwatersrand, Johannesburg, we visited South Africa in July and August last, and were given every facility for the study of the original fossils described as *Australopithecus africanus* Dart, 1925¹, *Australopithecus* (later *Plesianthropus*) *transvaalensis* Broom, 1936², and *Paranthropus robustus* Broom, 1938³, all probably of Pleistocene age.

Our report on the dentition and dental arches of the South African fossil man-apes has recently been completed and sent to the Pretoria Museum, but the importance of these 'near-men' in future discussions of the origin of man seems to warrant the present brief statement of our principal results.

The dentition of the adult forms described by Broom presents many transitional or annectant conditions between the pithecoïd and human stages. The upper canine tooth in a supposed female specimen referred to *Plesianthropus transvaalensis* has a smaller transverse diameter than the first upper premolar, and is altogether more human than ape-like. Although the upper canine crowns are broken off in the type specimen, the roots prove that these teeth were much smaller than those of apes. A well-preserved lower canine found in the same cave (at Sterkfontein) is remarkably small in comparison with those of typical modern apes; its crown has a

relatively low tip. This form of canine, which is sometimes nearly approached in certain female chimpanzees and orangs, would require but little additional modification to attain the human status.

The first upper premolar of *Plesianthropus* differs from that of typical apes in having a nearly symmetrical convex outer face and a generally human appearance; however, its buccal root remains distinct from the lingual, as in apes.

a gradual shift from the frugivorous food habits of primitive dryopithecine apes to the omnivorous habits of early man.

The facts and considerations cited in our fuller report can scarcely leave a well-founded doubt that the Pleistocene man-apes were survivors of the diversified *Dryopithecus* stock of the late Tertiary, which ranged from Spain to India and southward to East Africa, and that they were, in both a structural

RESTORED UPPER DENTAL ARCHES OF (A) *Sivapithecus sivalensis*, (B) *Plesianthropus transvaalensis*, (C) HEIDELBERG. (C) RESTORED BY PROF. J. H. MCGREGOR TO FIT THE KNOWN LOWER DENTAL ARCH.

The first lower premolar of *Paranthropus* has a rounded or ovoid crown, not unlike that of *Sinanthropus* and far advanced beyond the primitive condition in the lower Miocene *Proconsul*; here the first lower premolar has a compressed crown, the outer face shearing against the inner face of the upper canine. Transitional stages leading to the almost human first premolar of *Plesianthropus* are seen in the Siwaliks forms *Sivapithecus sivalensis* and *S. indicus*. With regard to its second lower premolar, *Plesianthropus* is intermediate between *Sivapithecus* and *Sinanthropus*.

The first and second upper molars of *Plesianthropus* are of the four-cusped type common to apes and man, but m^1 in the South African genera is very large, and even m^2 is much larger than in most men; moreover, m^1 is the smallest of the three. In the lower molars the length increases as we pass from m_1 to m_2 , as it does in primitive apes, whereas in man m_2 is usually shorter anteroposteriorly than m_1 . The lower molars of *Plesianthropus* exhibit a modified form of the five-cusped '*Dryopithecus* pattern'; but the principal grooves tend to arrange themselves as in the 'plus pattern' of typical man; cusp 6, which is barely indicated in some apes, is here prominent, as it is in some men.

A critical consideration of the evidence has led to the reconstruction of the upper dental arch reproduced in the accompanying figure. Its sides were slightly divergent posteriorly and it was well advanced in the human direction.

The crowns of the lower grinding teeth of the South African man-apes when well worn present nearly flat surfaces, as in man, whereas those of apes show steep elevations, especially on the inner side. These transitional conditions suggest that there was

and a genetic sense, the cousins of the contemporary human branch. Their numerous transitional conditions tend strongly to connect the families of apes and men at no very distant geological date (perhaps lower Pliocene). They seem to give no support to the idea of the separate existence of the human stock in early Tertiary times.

Effect of an Electric Field on the Viscosity of Liquids

FOR the past three years we have been working on the effect of an electric field on the viscosity of liquids. As the subject is now attracting attention, we think it will be well to give a preliminary account of our chief results. Experiments have been carried out with a method that permits a high degree of accuracy, with fields both transverse to and parallel to the direction of flow. The transverse field was applied with the liquid running in a channel of rectangular cross-section, the distance between the opposite charged sides, which were parallel to a high degree of accuracy, being about 0.2 mm.

The liquids used may be classified into those possessing no dipole moment, and those with a dipole moment. With non-polar liquids there is no effect. For example, with carbon disulphide and a transverse

field of 40,000 volts/cm., we have shown that any change in viscosity must be less than 1 part in 5,000. Other substances for which no effect has been established are benzene, chlorobenzene and various alcohols.

A marked effect, which presents several striking features, has been established with ten polar liquids (ether, acetonitrile, acetone, nitromethane, chloroform, and methyl, ethyl, propyl, butyl and amyl acetates). The viscosity increases with the field, but shows a saturation effect. A typical curve of the relation between field and change of viscosity is reproduced herewith for acetonitrile. The viscosity increases at first in a way roughly proportional to the square of the field, but later approaches a constant value which we call η_{∞} . In the case illustrated the limiting increase of viscosity is nearly 80 per cent.

With any one polar liquid the scale of the increase, determined by the value of η_{∞} , depends markedly on the purity, as measured by the conductivity k of the liquid. Repeated distillation diminishes both k and η_{∞} , and it has been established that η_{∞} is proportional to k . For example, with acetonitrile the limiting increases of viscosity are 115 per cent and 27 per cent for conductivities of 2.58×10^{-6} and 0.578×10^{-6} ohm⁻¹ cm.⁻¹ respectively.

In transverse alternating fields, the full static effect is obtained up to frequencies of about 400 ~. With higher frequencies, the effect decreases, and at frequencies of the order of 2,000 ~ there is no change of viscosity. The cut-off frequency increases as the temperature rises. No effect has been obtained in longitudinal fields of the same order.

An interesting effect which has been established is that the current through these badly conducting polar liquids (k of the order 10^{-6} ohm⁻¹ cm.⁻¹) does not obey Ohm's law. The current has certainly ceased to be proportional to the potential difference at fields of the order of 2,500 volts/cm., and tends towards a saturation effect. At higher fields there is a rapid rise in current, the whole curve of current against voltage being reminiscent of that for an ionized gas. The broken curve reproduced is typical.

The implications of these results will be discussed in a paper which awaits the completion of confirmatory results with a channel of different width.

Fundamental Vibration of a Rectangular Plate

THE *higher overtones* of vibrating plates sometimes combine when it so happens that the periods of two or more of them are very nearly equal. This phenomenon, which is of academic rather than of applied interest, has been fully studied for a free circular plate¹.

That the *graver tones* of the transverse vibrations may occasionally combine, would appear to be of importance in engineering resonance problems; the rectangular plate is a case in point. Two familiar sand nodal figures are shown in Figs. 1 and 2, of which the first is fundamental to a narrow, and the second is fundamental to a wide free rectangular plate. The frequencies for the particular brass plate employed were very nearly equal, 558 and 548.8 c./sec. respectively. By filing the longer side of the plate, the two periods were adjusted to equality with the aid of a valve oscillator. This resulted in a profound change in the form of the vibrating surface (see Fig. 4), the former nodal systems being no longer obtainable. A pattern which is the mirror image of Fig. 4 can also be obtained. The sharpness of resonance, which is an inverse measure of the 'damping capacity' of engineering practice, is considerable. Thus a change of only 1 c./sec. one way or the other in the tone, produced the modified nodal patterns of Figs. 3 and 5.

That these curved nodal lines are due, neither to a want of uniformity in the plate, nor to absence of

freedom in the vibration, is proved by the fact that as soon as the same plate is excited in another mode (see Fig. 6), a characteristic single nodal pattern is

obtained. The ratio of length to breadth in Fig. 4 is 1.93. I estimate that a combination between the nodal systems of Figs. 2 and 6 should occur when this ratio is about 3.9.

Relation between Specific Heat and Temperature for Nitrobenzene

THEORETICAL considerations lead to the conclusion that traces of impurities can have an influence on the dielectric constant and density of a substance, but the changes of energy are only very slightly affected by them. For these reasons, the relation between specific heat and temperature for nitrobenzene has been investigated, with special attention to the neighbourhood of the solidification point of this substance.

This work is analogous to that carried out at the Kamerlingh Onnes Laboratory in Leyden on helium. It was then found that at the transition point of helium the change of density was 0.3 per cent, that of the dielectric constant 0.1 per cent, but the change of specific heat was as much as 79 per cent in certain temperature limits.

Two samples of nitrobenzene were used. One was purified by Dr. W. Keesel, of the Joseph Pilsudski University in Warsaw, the second by myself. The apparatus was similar to that used by Prof. W. H.

Keesom and Dr. Olusius¹ in Leyden. Before measurement, the nitrobenzene was distilled directly into the calorimeter. The energy increments were made small so as to be able to observe the possible transition point.

The experimental results show that the change of the specific heat of nitrobenzene with temperature is linear and this relation can be represented by the following equation:

$$C = 0.33830 + 0.000556 t.$$

It should be emphasized that observations in the neighbourhood of 9.5° C. were made with especial care, the points of the curve being 0.3° C. from each other, all lying on a straight line. The results obtained are in perfect agreement with those of other authors², especially with the data of Williams³ and Daniels⁴.

The relation of the refractive index to temperature and the heating curve were also investigated in the temperature limits 5.7–20° C., but no anomalous behaviour was observed.

After-Image Phenomena

If in a dark room a light be attached to a scale, and a point three feet on the right is marked with a peg and the light be looked at with one or both eyes for one or two seconds from a distance of ten feet and then the eyes be directed at the peg, it will be noticed that the negative after-image of the light is seen on the peg but the positive after-image has rapidly passed it to the right. The eyes being firmly directed towards the peg, it will be noticed that the positive after-image comes rapidly back towards the peg.

The first part of the experiment I have described before; it is evidently due to the contraction of the eye muscles pressing on the eye and moving the photo-chemical fluid, thus causing a separation of the positive and negative after-images. The second part of the experiment appears to be due to the cessation of the pressure on the eye causing the photo-chemical fluid to flow in the opposite direction. It should be noted that the pressure is in the opposite direction to the movement of the image; thus when the pressure is to the left, the image moves to the right, corresponding to the new position of the fluid in the retina.

Ultra-Violet Spectrum of Thiophosgene

We have tried to solve the problem of the fundamental vibrations of thiophosgene by analysing one of the three band systems found by one of us¹ previously in the ultra-violet spectrum of the vapour. The first system is composed of more than five hundred bands distributed between 5712 and 3989 Å. at ordinary temperature. A second and a third

system appear between 3282 and 2710, and beyond 2710 Å. respectively. Their complete analysis is in progress.

The main feature of the first system, observed when the dispersion is sufficiently high, is the fact that each band is resolved into two or sometimes three components. It is easy to see that we are dealing with isotope effects originating from the Cl atoms. As a matter of fact, the same phenomenon has already been observed by one of us² in the case of phosgene and has been assigned to the above cause through direct experiments by W. Kuhn³.

The following formula enables us to calculate all the bands of the system in satisfactory agreement with the observed frequencies:

$$\nu = 17374 + 914\nu_1' - 3\nu_1'' + 240\nu_2' + 400\nu_2'' - \nu_3'' - 1148\nu_4' - 537\nu_4''$$

Thus the absorption spectrum of thiophosgene is characterized by five fundamental frequencies: 1148 and 537 cm^{-1} for the normal molecule and 914, 240, 400 cm^{-1} for the activated state.

As the molecule belongs to the symmetry group C_{2v} , it is possible to assign these values to the various possible vibrations in the following way:

$$\nu_1'' = 1148, \nu_1' = 537, \nu_2' = 914, \nu_2'' = 240, \nu_3' = 400$$

The nomenclature is identical with that used by Bailey and Hale⁴ in the case of phosgene.

It is worth mentioning that our analysis was made at a time when no data were available for the Raman or infra-red vibration frequencies of the thiophosgene molecule. Our formula has been derived from the measurements by determining the distribution of intensities, considering quantitatively the isotope effect and

by applying the rules of Herzberg and Teller⁵. It is only recently that the Raman spectrum of liquid thiophosgene has been measured, namely, by H. W. Thompson⁶. His data confirm our results for the normal molecule both with regard to magnitude and assignment: $\nu_1' = 1121$ and $\nu_2'' = 497$. The slight difference may be due partly to the fact that our figures refer to the gaseous and not to the liquid state of the thiophosgene molecule.

It is further of interest that even the values of $\nu_2' = 287$ and $\nu_2'' = 363$ given by H. W. Thompson are not very different from our figures for ν_2' and ν_2'' , although these latter belong to the excited and not to the ground state as in Thompson's experiments. This coincidence is obviously due to the fact that the electron excitation is located in the C-S bond. Incidentally, with the elucidation of the thiophosgene spectrum, our experiments provide, as results of more general interest, a check on the validity of the Herzberg-Teller theory and a justification for the use of the isotope effects in the study of complex spectra.

Details of our experiments will be published elsewhere.

Points from Foregoing Letters

STATISTICAL analysis of the results obtained in ten laboratories give a value of 1,670 for the conversion factor for calculating from spectrophotometric observations the biological effect of halibut liver oil (containing vitamin A); therefore Miss E. M. Hume considers that the conversion factor of 1,600 provisionally adopted by the Second International Conference on Vitamin Standardization in 1934 should be retained, although marked discrepancies have been observed in the United States, in connexion with the United States Pharmacopoeia reference cod liver oil, which gives a higher conversion factor (about 2600).

The time of recovery of vision after looking at a bright light has been determined by Dr. L. B. Pett for 1,200 people by means of a new apparatus and found to depend upon the amount of vitamin A taken with the food. The author also gives a table showing a certain correlation between recovery time in the visual test on one hand and dry skin, night blindness and liability to colds on the other.

Laccase, an oxidizing enzyme found in the latex of *Rhus succedanea*, is found by Prof. D. Keilin and Dr. T. Mann to be a copper-protein compound belonging to the same group as the polyphenol oxidase of potatoes and mushrooms, but differing in its blue colour and other respects; for example, it oxidizes ascorbic acid directly, does not oxidize *p*-cresol and is not poisoned by carbon monoxide.

Dr. O. E. Georgi and A. E. Beguin find that there is no correlation between the amount of indole-acetic

acid (heteroauxin) produced in synthetic media, in presence of tryptophane, by various strains of *Rhizobia*, and the ability of these strains to induce the formation of nodules on the roots of leguminous plants.

From a study of the dentition and dental arches of the South African fossil man-apes, Prof. W. K. Gregory and Dr. M. Hallman conclude that these Pleistocene man-apes were derived from apes at no very distant geologic date, perhaps Lower Pliocene, and that the evidence does not indicate the existence of human stock in early Tertiary times.

A graph showing the change in viscosity of acetonitrile under the influence of an electric field, is submitted by Prof. E. N. da C. Andrade and O. Dodd. Similar results were obtained with ether, acetone and other polar liquids; with non-polar liquids there is no effect.

Nodal figures obtained with rectangular brass plates, showing that the *groover tones* of the transverse vibrations may occasionally combine, are submitted by Miss Mary D. Waller.

The change in the specific heat of specially purified nitrobenzene with temperature is found by Dr. J. Masur to be linear over the range 5°–20° C.

The ultra-violet spectrum of thiophosgene has been investigated by Prof. V. Henri and Dr. J. Duchesne. The vibration frequencies calculated for the normal molecule agree with those since published by H. W. Thompson, derived from a study of the Raman spectrum.

Kazak Social Structure

MR. ALFRED E. HUDSON has examined the nature of certain features of Turco-Mongol social structure, investigating the processes which appear to have been active in their development ("Kazak Social Structure", *Yale University Publications in Anthropology*, No. 20. Yale Univ. Press, and Humphrey Milford, 1938. Pp. 109. Price 1.50 dollars). Most of the material utilized relates to the middle nineteenth century, immediately before the Russian conquest of Central Asia; but the author also bases his work on investigations in the field in 1936. The Kazak, or Kirghiz, are a nomad stock-herding people, though now becoming sedentary. They inhabit the steppe country lying between the Caspian and the Altai Mountains, and number, according to the 1926 census, 3,959,000. They are divided into a large number of tribes, sub-tribes, gentes and branches, of which the structure and relation one to another are not clear. As the result of this investigation, after consideration of the various aspects of Kazak social life into which they enter, it would appear that there is a constant tendency towards the division of existing groups by branching, and at the same time a movement towards the formation of larger groups from the smaller by fusion. Although increasing numbers was the underlying cause of fission, the immediate causes were various. New economic units arose, for example, from the custom of giving a son a share of his father's cattle, favouring the centrifugal tendency. In the formation of larger units, groups of individuals, who belonged to other gentes, were absorbed, or subordinate or vassal gentes might be formed, leading to a symbiosis, rather than a political union. Political amalgamation frequently cut across genealogical lines. While some unions were for mutual protection, others were the result of force. In this third type it is difficult to distinguish between voluntary and involuntary amalgamation. The prestige of a leader acted as a magnet. In practice the solidarity of the blood-group was subservient to the domination of the wealthy and powerful individual. The personal dependence of the weak on the strong and wealthy was more effective than the responsibility of the members of the blood group for one another.

Petroglyphs and Tuareg Origins

In 1926, the Hon. Francis Rodd directed attention to apparent similarities between certain rock drawings in the Aïr mountains of the southern Sahara and the pictures of Libyans in Egyptian tomb decorations, etc., of the Nineteenth and Twentieth Dynasties. The question of whether the Tamahu, and Tehenu of the Egyptian records were related to, if not the actual ancestors of, the Tuareg, was discussed by Orio Bates. Mr. Rodd now points out (*J. Roy. Anthropol. Inst.*, 68; 1938) that the human figures which appear in these petroglyphs can be divided into categories, according to the method of portrayal. Four types can be distinguished: (1) The 'hour-glass' group, which recently has become explicable as represented in the archaic leather dress of the 'wild

men, of the Ahaggar and Aïr, who live remotely in the fastnesses of these mountains, possibly remnants of a pre-Tuareg, non-negroid people; (2) the 'demon' or 'imp' figures, having nothing in common with the other groups except hair decoration; (3) decorated figures, with an elaborate dress, in which an attempt is made to portray a patterned or chequered garment with a yoke or ornament at the neck, and having certain analogies in Tehenu Libyans of the Egyptian tombs; and (4) the 'riding-breeches' group. Nos. 3 and 4 appear to be contemporary, though their heads are strikingly different in shape. It has been suggested that the 'riding-breeches' type represents the women of group 3. Neither type shows the mouth, which may be an attempt to represent the Tuareg veil, although the Egyptian Libyans have the mouth fully represented. Tentatively it is concluded that group 2 may be an aboriginal pastoral, or hunting people, slaves or subjects of group 1, that is if they are their contemporaries. Group 3 may be the Libyans of the Egyptian tombs. They wear feathers in their hair, with the Libyan lock on each side of the head. They possess spears and javelins, round shields and horses. Group 4 may be women or men. If the latter they are of a different race from Group 3; if they are women, they are the women of group 3, in which event they ought to be Amazons, as they wear feathers in their hair, one Libyan lock and possess spears, javelins, round shields, and horses. If group 3 represent the ancestors of the Tuareg, it shows the survival of the same costume over a very long period, and makes the migration of the Tuareg to Aïr much earlier than has been thought.

Antirabic Immunization

I. J. Kligler and H. Bernkopf (*Brit. J. Exp. Path.*, 19, 378) report experiments showing that intraperitoneal injection of formalized tissue cultures of rabies virus has considerable immunising capacity for mice. Immunity to intracerebral infection was incomplete, and about 42 per cent showed no immunity after five to seven injections of the vaccine. Immunity was established more readily by intraperitoneal or subcutaneous infection. Immunized mice which survived an intraperitoneal infection were found to possess a greater degree of immunity than untreated mice which survived infection. Primary treatment with inactive virus affected in a marked degree the immunity of the mice to an intracerebral infection. Mice which received diluted vaccine (1:10) or fewer doses possessed a lower degree of immunity than the others, although they all survived intraperitoneal or subcutaneous infection with fresh brain virus. Only half the mice which survived intraperitoneal infection without previous vaccination proved immune to intracerebral infection, whereas 84 per cent of previously immunized mice were found to be immune. Intraperitoneal injection of a single dose of a rabies virus culture which had a very low virulence for mice conferred on the treated mice a high degree of immunity against a subsequent intracerebral infection with test-brain virus.

Absorption of Sulfanilamide

E. K. Marshall, jun., and W. C. Cutting (*Bull. Johns Hopkins Hosp.*, 63, 328; 1938), of the Department of Pharmacology and Experimental Therapeutics, Johns Hopkins University, made the following studies of the absorption and excretion of sulfanilamide in the mouse and rat. Blood concentration curves were determined in these animals after administering sulfanilamide in different doses, in different vehicles and by different routes. The percentage excretion of the drug in eight hours by the kidney was determined, as well as the amount remaining unabsorbed in one hour in the intestinal tract. From the data obtained, it was concluded that the excretion was more rapid in the mouse than in the dog, rat or man. No significant difference was found when sulfanilamide was administered by different routes or in different vehicles. When large doses were given the maximum concentration in the blood of the rat was much lower than in the mouse.

The Glasshouse Leaf-Hopper

MR. G. FOX WILSON has collected much information about the glasshouse leaf-hopper, *Erythroneura (Zygina) pallidifrons*, in a recent short paper (*J. Roy. Hort. Soc.*, 63, Pt. 10, Oct. 1938). The pest appears to have assumed serious proportions, and causes widespread damage to the leaves of many glasshouse plants. *E. pallidifrons* has been known for many years, but was first erroneously named *Zygina parvula*. Taxonomy, life-history, methods of feeding, and host range, are discussed in the paper, and control measures have also been investigated. Eradication is difficult, but the use of nicotine-soap wash offers the greatest possibility of success. The use of darris, pyrethrum extract or eucalyptus oil, and also fumigation with nicotine vapour or hydrocyanic acid gas, are alike in their inadequate control of the pest. An infestation may often be checked by removing the lower leaves of plants which are attacked, crushing the larvae under the upper leaves, and removing weeds, particularly chickweed, which harbour the insect.

Pathogenic Yeasts

THE non-sporing yeast *Mycotorula albicans* is frequently associated with other fungi in various diseases of human skin. Its distribution as a parasite is apparently widespread, and Messrs. P. Redaelli, T. Castelli and R. Ciferri have shown (*Mycopathologia*, 1, Fasc. 3, Sept. 1938) that it can be isolated from various Italian home-made bread yeasts. It does, in fact, perform the alcoholic fermentation of a leavening agent. There would seem little danger to human beings from eating bread baked with such mixed yeast, but as a source of infection it cannot be overlooked. Another non-sporing yeast, *Blastodendron Krausii*, has also been isolated from the same kind of yeast. It also can accomplish alcoholic fermentation of glucose, levulose and maltose; but as yet is not a proved parasite of human beings.

Agaricaceae of Hokkaido, Japan

THE second part of a very detailed study, by Sanshi Imai, of the gilled fungi of Hokkaido, Japan, has recently appeared (*J. Fac. of Agriculture, Hokkaido Imperial University*, 43, Pt. 2, pp. 179-378, Aug. 1938). The first part, which was noticed in

these columns (*NATURE*, 141, 1105; 1938) was published in March of this year. This second part completes the account of Agaricaceae, and raises the number of new species to forty. 348 kinds have, in all, been described critically. 238 of these are already known in Europe and North America; 49 species have previously appeared in Europe only, and 23 in North America. 43 species are indigenous in eastern Asia, and 196 species are new to Japan. Many fungi in Hokkaido are intermediate between European and North American species, thus giving additional confirmation of an ecological connexion with both regions. Edible and poisonous species are enumerated, but the account is of international value for its critical nature and its proposals for further subdivisions in existing classifications.

Mould Fungi of the Soil

DR. MARIE E. CAMPBELL has made a detailed study of Mucorales in the soil (*Trans. Roy. Soc. Edin.*, 59, Pt. 2, 411-436; 1937-1938). Twenty-three species of this group of mould fungi have been isolated from seven samples of soil, and some conclusions of general mycological interest have been reached. Twenty of the species were heterothallic, and the remaining three homothallic. A hybridization, though somewhat imperfect, has occurred between the negative form of *Abisidia cylindrospora* and the positive form of *Rhizopus nigricans*, thus adding possible interthallic crosses as another taxonomic difficulty to those already overwhelming the mycologist. Positive forms of the Mucorales are, in general, distributed more widely in soil than the negative strains, and there are indications that moorland and peaty soils contain fewer species of these fungi than cultivated fields. Many other details of culture, of spore longevity, of structure, of the effect of soil reaction and other factors, are given in the paper, which is further elucidated by fifteen text-figures and three excellent plates.

Thorough Cultivation of Soil

IN most countries, and especially in Great Britain, farmers have a traditional belief in the necessity and virtue of thorough cultivation. Although it is self-evident that some cultivation is needed to secure a satisfactory tilth, it is not certain that additional and deeper workings of the soil are as valuable as has been generally thought. At the present day when cultivation is one of the heaviest expenses on the farm, the question clearly needs reconsideration, and Dr. B. A. Keen has recently given some interesting results of investigations on the subject (*J. Min. Agric.*, 45, 645; 1938). Experiments carried out over a number of years on heavy land showed that deep ploughing or subsoiling was of little or no benefit to a sugar beet crop, while extra ploughings, though they produced some small increase in the yield of the potatoes and sugar beet, were also uneconomic operations. Similarly, intensive inter-row cultivation of root crops, hitherto regarded as desirable, proved a waste of labour on both heavy and light land. The practice of rolling and harrowing cereals, on the other hand, was supported by experimental evidence. Rotary cultivation received special attention, comparison being made between plots prepared by the plough, the grubber and the rototiller. Germination tended to be quicker on the loose seed bed from the rototiller, but subsequent growth and yield were

very similar on all three sets of plots. If time presses, therefore, the quicker and cheaper process of grubbing can safely be substituted for ploughing, but the practice should not be continued for several years in succession, as weeds are liable to increase rapidly. The conclusion that, beyond a certain minimum, cultivation has little influence on crop yield has also been reached from experiments carried out on different soils and under different climatic conditions, but still further work is needed to determine if the results are of general application, or are typical of certain types of soil and climate only.

Helium Ratios of the Quincy Granite

It is well known that the helium ratios of acid rocks, especially if coarse-grained, are usually much smaller than those of fine-grained basic rocks of the same geological age. A systematic programme of research to discover the source of these anomalies is being carried out by N. B. Keevil, and a report of his results on the Quincy granite and its minerals has recently appeared (*Amer. J. Sci.*, 406-416, Dec. 1938). The 'ages' computed from determinations of the helium, uranium and thorium contents are: quartz, 86 ± 5 ; riebeckite and aegirine, 86 ± 5 ; and alkali feldspar, 49 ± 3 million years. The weighted 'age' calculated from these data and the mineral composition is in agreement with the 'age' determined from the granite itself—62 million years. A similar low 'age' for a Pre-Cambrian labradorite from the Adirondacks (101 ± 10 million years) suggests that leakage from feldspars may be prevalent. Judging from the high degree of alteration of the Quincy feldspar, the loss of helium in this case is ascribed to excessive crystal imperfections. Though the concentrations of helium and radioactivity in the riebeckite and aegirine are five times as high as in the other minerals, a relatively high 'age' was obtained, indicating that there has been no tendency for helium to diffuse towards a uniform concentration during the history of the rock. Further experiments are in progress to show whether low helium 'ages' may be due to leakage from feldspar, and whether the most reliable results on rocks are to be obtained from quartz and the ferromagnesian minerals.

Geochemical Data of Southern Africa

DR. A. L. HALL has made a very valuable compilation of chemical analyses of rocks, minerals, ores, coals, soils and natural waters from Southern Africa. Geologists and others will welcome its publication by the Geological Survey of South Africa (*Mem.* 32, p. 868; 1938), particularly as the 5,983 analyses have been drawn from a widely scattered literature. Part 1 deals with material occurring within the Union of South Africa and South West Africa, while Part 2 covers the Rhodesias, Kenya Colony, Tanganyika Territory, Uganda, Nyasaland, the Belgian Congo, Madagascar, Mozambique, etc. The rocks analysed have been roughly classified as acid, intermediate, alkali, basic and ultrabasic, sedimentary and metamorphic, and as differences of opinion on matters of classification may introduce difficulties in running down particular analyses, a detailed index is provided. It is very convenient to have in one volume all the analyses (up to the beginning of 1936) of such petrologically important provinces as those of the Bushveld, the kimberlite pipes, the Karroo dolerites and lavas, the rift valleys, and other alkali-

complexes. In this and other geochemical fields the volume will be of service in indicating where further chemical investigation is desirable, in preventing overlapping of analytical effort, and as a guide to the sources of information.

Tri-alkyl Derivatives of Lead

F. Hein and A. Klein have recently described a greatly improved method of preparing lead tri-ethyl and lead tri-methyl (*Ber. deutsch. chem. Gesells.*, Nov. 1938). The electrolytic method described by Midgley, Hochwalt and Calingaert in 1923 gives very low yields. This is due to the solvent action of alcohol on the product, which becomes transferred to the oxidizing action at the anode. By substituting 2N caustic alkali for alcohol a greatly improved yield results as the lead tri-ethyl is insoluble in water. Moreover an alkaline solution of lead tri-ethyl chloride can be used as electrolyte instead of previously isolating the hydroxide. The product separates in an almost pure condition at the lead cathode, but when pure water was substituted for alkali only lead and hydrocarbons were formed at the cathode. The appearance of troublesome by-products at the anode and the very slow formation of oily drops near the cathode before the application of the current led ultimately to the discovery that the tri-ethyl lead can be obtained easily, rapidly and almost quantitatively by a purely chemical method, namely, by reducing the alkaline solution of lead tri-ethyl chloride by metallic aluminium, lead or zinc at the temperature of the water-bath. After drying the oil with sodium sulphate it was analytically pure. When tin was substituted for aluminium, lead or zinc, an unstable substance, presumably lead di-ethyl from its scarlet colour, was formed but not isolated. No data are given as to the molecular complexity of the compound which was found by Midgley, Hochwalt and Calingaert to associate to the dimeric form in benzene except in dilute solutions.

Photochemical Theory of Vision

No. 583 of Messrs. Hermann's Series of *Actualités Scientifiques et Industrielles* (Paris) is the fourth of the biophysical series, and is entitled "La Base chimique et structurale de la Vision". It is written by Selig Hecht, professor of biophysics in Columbia University. It brings together a large amount of quantitative work which has been done on human and other eyes during the last ten years and shows that it is consistent with a simple photochemical theory of vision. According to this theory, there is initially in each cell of the retina a quantity a of a substance sensitive to light, and if light of intensity I has acted on it for t seconds and has converted x of the substance into photoproducts, which may combine with themselves or with other products to re-form the original sensitive material, the rate at which x increases with time under the action of light I is equal to $k_1 I(a-x)^m - k_2 x^n$ where k_1 and k_2 are constants, and m and n are 1 or 2 according to whether the reactions are mono- or bi-molecular. Curves are given showing how the least increment of intensity of light detectable under various conditions depends on I for each of the possible values of m and n and for both rods and cones of the retina, and the author shows how recent observations enable the values of m and n to be determined.

Scattering of Wireless Waves in the Ionosphere

By T. L. Eckersley, F.R.S.

THE purpose of this note is to direct attention to the real nature of the scattering of wireless waves in the ionosphere.* Particulars have been given in several papers (see references), but their significance does not seem to have been generally realized.

The essential facts are as follows:

(1). The echo pattern received on a linear time base near a high-power pulse transmitter on a frequency above the critical frequency is practically without exception of the type given in Fig. 1, in which the ground pulse *G* is followed by echoes at *P* which occur momentarily at apparent equivalent heights of 80–300 km., and a more distant irregular scatter group *S*. This group, while continually changing in detail, forms a permanent system of

Fig. 1.

echoes, having a well-defined leading edge *Q* with an equivalent height between approximately 600 km. and 2,500 km. and extending until it is finally lost in the background noise. It is this group which forms the

*We are not here concerned with the 'broadening' of *F* echoes often observed at night.

Fig. 2.

Fig. 3.

(a) GROUND SIGNAL, *G*; (b) GROUND SIGNAL MAXIMUM; SCATTER, *S*. (c) GROUND SIGNAL SUPPRESSED; SCATTER SUPPRESSED; SCATTER MAXIMUM.

echoes of apparently great equivalent height which have been recorded by other workers.

(2) Spaced-frame experiments, which determine the direction of arrival of the echoes, show that the echoes in the scatter group *S* are never reflected vertically when the frequency is above the critical frequency, so that the delays of these echoes on the ground pulse do not represent equivalent vertical heights.

(3) The apparent equivalent height of the leading edge *Q* is a function of the frequency, and a typical curve is shown in Fig. 2. As the frequency is reduced, so that it approaches the critical frequency at vertical incidence, this equivalent height approaches that of the second order *F*₂ reflection, and the direction approaches the vertical. Thus the maximum equivalent height at which the scatter echoes are received vertically is associated with the second order *F*₂ reflection.

(4) If a beam transmitter is used, energy is scattered back from the direction in which the beam is pointing. This effect was explained by Mr. Tremellen in 1927, and we have verified it by numerous experiments since. Instead of using special high-power pulse transmissions to observe

the scatter, as in Fig. 1, use can be made of commercial morse transmitters by choosing times when they are sending regularly spaced dots. Fig. 3 shows a set of photographs of such a morse dot observed on a linear time base when the speed was 25 cycles per sec. The transmitter was situated at Ongar, Essex, and had a beam directed on Salisbury, in South Africa. The frequency was 19.5 Mc./sec., and so was well above the critical frequency. The receiver was an Adcock direction finder situated only a few kilometres to the east at Chelmsford, and a strong ground signal was received from a direction nearly at right angles to the

direction of the beam. In (a) the scattered signal can be seen overlapping the ground signal and extending beyond it. This scatter was found to be strongest when the ground signal was suppressed as in (c), and was itself suppressed, nearly at right angles to this direction, as in (b), at the maximum of the ground signal, when the goniometer indicated an almost southerly direction.

(5) The distant scatter group *S* disappears when the frequency is so high that the ray which leaves the earth tangentially escapes through the *F* layer.

These five facts can only be explained in one way. Rays of frequency considerably greater than the critical frequency follow an oblique path, passing through the *E* layer on their upward path at *A*, and on their downward path at *B* after reflection at the *F* layer, as in Fig. 4. Experimental evidence⁵ shows that the *H* layer is always full of irregular scattering clouds. Signals received at or near the transmitter are those which have been scattered back along their original outward path at *A*, giving rise to echoes of the type *P*, and at *B*, producing the distant

scatter group *S* shown in Fig. 1. The results given in (5) above prove that there are no scattering clouds in the *F* layer similar to those in the *E* layer.

Fig. 4.

All these results are based on very numerous observations carried out over a number of years.

Structure of Proteins

DESPITE the cold weather and the proximity of Christmas, some hundred and thirty people attended a meeting of the Physical Society on December 20 at which Dr. Irving Langmuir delivered an address on the structure of proteins. He began by enumerating the facts which pure chemistry had succeeded in accumulating about these substances, which play such an important part in living Nature. By the union of two amino acids, with the elimination of a molecule of water, the polypeptide unit is built up. Chemically, this has two valence bonds free, one at each end, and thus seems adapted solely for the formation of chain compounds. If proteins are indeed chain compounds, it would be difficult to understand why they have apparently definite molecular weights (often multiples of 18,000), or why the molecule behaves approximately as a spherical one.

A few years ago, Dr. Dorothy Wrinch suggested that, instead of the polypeptide unit (I),

where *R* is one of a number of radicals, the unit might really be (II), which differs from it only in the position of a proton within the molecule. It has, however, four free valency bonds, which (being attached to nitrogen or carbon atoms) make angles of 109° with each other. Investigation of the spatial arrangements possible with such a unit shows that they can form closed 'cages', the plane sides of which are constructed of a lacework of hexagons. The discrete molecular weights (and indeed the ratios of these) thus receive a natural explanation, as does the approximately spherical shape of the molecule.

One cage in particular contains 288 amino-acid residues, which is equal to the number determined by physico-chemical methods in the case of egg

albumin, within the limits of accuracy of these methods. In this particular case, the cage is a truncated tetrahedron which does not differ greatly from an octahedron.

Now proteins can be 'denatured' by various mild treatments (shaking for three or four minutes, or heating to 85° C. for one or two minutes are sufficient in some cases) and then show markedly different properties from native proteins, but no change in molecular weight. It is suggested that these denatured proteins are in fact composed of the polypeptides which the chemist had discovered, since the treatment which he necessarily applies in order to make investigations would be sufficient to cause the change. The ease of denaturation, and the great alteration in properties, both follow naturally from this hypothesis, taken in conjunction with the 'cyclo' hypothesis adopted for native proteins.

A particularly interesting fact which receives explanation by these theories is the insolubility in water of mono-molecular layers of proteins formed from soluble native proteins. The explanation lies in the positions of the side chains *R*, which in the cage structure are arranged around the edges of the hexagonal lacunae composing the plane sides of the cage, whereas in a mono-molecular layer, the cage is developed into a plane. When *R* is hydrophobe, the mono-molecular layer is formed with these radicals projecting; in the 'cage' they project into the interior and are thus marked.

The last part of the lecture was devoted to the X-ray evidence, which is most complete in the case of insulin, since as shown by Crowfoot, this particular protein has but one molecule per unit cell, and the results are therefore more easily interpreted than would be the case with most proteins.

Dr. Langmuir stressed the point that the X-ray data, like many of the other facts explained by the theory, such as the appearance of α - but no β -amino acids, were not used as data in constructing it originally; nevertheless, the results of the X-ray

investigation, in Dr. Langmuir's view, confirm many features of the structure to which the theory had led.

In the discussion which followed the address, Dr. Wrinch explained that the method used by Langmuir and Wrinch in interpreting the vector maps was a geometrical formulation of the classical picture of a crystal as a set of discrete units. Prof. J. D. Bernal uttered a word of caution against supposing that the theory was proved. He thought that certain features

must be true, and others were possibly true, but in his view the X-ray data fail to confirm the proposed structure. He had had a vector map calculated for the latter, and found that it differed very markedly from that obtained experimentally. Prof. E. H. Neville showed the care that is needed in interpreting a vector map, by a simple example in which a map constructed from a given set of points appeared at first sight to correspond to quite a different type of distribution.

Studies in Galactic Structure

IN *Bulletin of the Astronomical Institutes of the Netherlands*, No. 308, J. H. Oort investigates the structure of the galactic system from counts of faint stars in medium and high galactic latitudes combined with absorption data from Hubble's counts of extra-galactic nebulae. Data for the star density were derived from Kapteyn's Selected Areas; the amount of absorption to be used for each selected area was estimated from nebular counts in neighbouring fields.

Assuming tentatively that the absorption occurs in front of the stars studied, the investigation leads to a picture of the galactic system differing somewhat from the prevalent conception: broadly, the sun appears to be situated in a region of relatively low star density surrounded in all galactic longitudes by extensive regions where the density is at least twice as high.

The structural features indicated are large-scale phenomena, extending on both sides of the galactic plane to distances of 500 or 700 parsecs (say 1600–2300 light years) from this plane. The analogy between this structure and the spiral structure of strongly flattened extra-galactic systems is discussed; but the data are insufficient to define the course of the spiral arms, although the sun apparently lies between two arms. At greater distances from the galactic plane, the unevenness in density distribution disappears; at levels between 800 and 1800 parsecs the equidensity surfaces are satisfactorily represented by planes inclined at angles of about 10° to the galactic plane, implying an increase of density in the direction of the galactic centre by a factor 1.38 per 1000 parsecs. The derived longitude of the centre is $324^\circ \pm 3^\circ$ (region of Scorpio-Sagittarius), in excellent agreement with the longitude derived from

the effects of differential rotation or from the distribution of globular clusters and planetary nebulae. As regards selective absorption, the evidence from colour-excess data in the Kapteyn Areas points to a strong galactic concentration of the absorbing clouds, and indicates that the greater part of the absorption derived from Hubble's counts of nebulae must have occurred relatively close to the galactic plane.

From the time of Sir William Herschel, the dark patches and lanes, more or less devoid of stars, in the Milky Way have been an attractive problem for astronomers. It is now known that these dark areas must be due chiefly to clouds of cosmic dust. In Publication No. 48 of the Kapteyn Astronomical Laboratory at Groningen, an estimate is made by B. Hiemstra of the distances of some absorption clouds in areas 2, 5, 9 and 24 of Kapteyn's Selected Areas.

From a statistical study of proper motions and apparent magnitudes of the stars in the absorbing regions and in the surrounding rich areas, the author is able to derive limits for the distance and absorption effect of the clouds, assuming them to be of infinitesimal thickness compared with their distance. The results range as follows: Area 5 contains a cloud absorbing 0.8^m – 1.5^m at a distance less than 300–400 parsecs. Area 2 contains a cloud absorbing at least 0.5^m at a distance of 600–1200 parsecs. In area 9, lying east of the North America Nebula, the absorption reaches 2.0^m at a distance of 600–650 parsecs. The plates used in the investigation were taken at the Radcliffe Observatory, Oxford, with the 24-inch refractor, which was recently presented to the University of London Observatory at Mill Hill. Usually the pairs of plates were taken about fifteen years apart.

Education for Citizenship

PREPARATION for and training in citizenship are recognised by an increasing number of people in Great Britain as of vital national importance and as calling urgently for the development and extended application of effective techniques. There is much to interest them in "Forums for Young People", a pamphlet recently issued by the United States Office of Education (Washington, D.C., Superintendent of Documents, 15 cents). This is a study of problems and plans involved in providing organized series of free discussions of public affairs for high school and college students and for other young people. For two years, the Commissioner of Education has conducted, with the help of very

substantial Federal grants, a vigorous propaganda for the organization of public affairs forums throughout the States, and the resulting experiments have provided ample material for this study, the publication of which, will, he hopes, "contribute to the thinking of the teaching profession and of laymen on this problem of finding ways and means to make secondary and higher education meet its civic responsibilities". It begins with an admirably lucid discussion of pros and cons. The point of view taken is that the most important purpose of education in our time is the training of the mind to deal intelligently with the undecided issues which face mankind. Subsequent chapters describe: types of forum

programmes for high schools, forum plans for colleges and universities, forum plans for youth on community-wide basis and "guide-posts to organisation".

Some of the problems of "Forums for Young People" were discussed at the Secondary School Conference held by the Association for Education in Citizenship last year at Morley College, London. A report of the proceedings at this conference appeared in the July number of the *Citizen*. The conference covered a wider field, including consideration of the part played by character and purpose in the making of good citizens, and the efficacy of various out-of-school activities such as scouting, classes in first-aid, and camping as means for stimulating emotion and imagination and harnessing them to action in the service of the community so as to overcome "that apathy which is the besetting weakness of democracy". With the view of keeping in touch with one another the now considerable number of schools where systematic efforts are made to foster the development of a spirit of community service a "Schools Community Service Group" has been constituted within the Association with headquarters at

The Downs School, Colwall, Malvern, with Mr. W. F. Hoyland as honorary secretary. The chief subjects dealt with by the group are: manual work on the school estate, help at physical training and play centres, boys' clubs and school missions, visits to factories, housing estates, etc., work camps in the holidays, for example, helping unemployed men on their allotments, school expeditions abroad.

In the same number of the *Citizen* is an article of outstanding interest by Prof. René Maheu of the Institut Français du Royaume-Uni on the teaching of philosophy in French secondary schools. The philosophy teachers are, it appears, allowed the greatest freedom both as to method and as to subject, and most of them concentrate on instruction "not so much in facts or ideas as in the sovereign art of passing judgment". They seek to equip their pupils with the techniques of self-knowledge and of objective thinking. To them is available the sole opportunity given to secondary school teachers of "effectively helping their pupils to decide for themselves with their own reasoning powers, the use they are to make of their freedom as citizens".

The Differential Analyser in Electrical Engineering

IN recent years, there has been a considerable development in the design and use of mechanical and electrical instruments for carrying out calculations of various kinds. These calculations can be divided into two main groups: first, there are those which consist of the four processes of arithmetic (addition, subtraction, multiplication and division) combined in any way, and secondly there are those which involve the further ideas of the calculus. For the latter group of calculations, the solution of differential equations is one of special importance both in pure and in applied science, as in both fields there arise many kinds of differential equations which have no formal solution or none convenient for numerical evaluation, but for which quantitative information about the behaviour of the solution is required.

In a paper by Prof. D. R. Hartree and Mr. J. K. Nuttall on the differential analyser and its applications in electrical engineering (*J. Inst. Elec. Engineers*, No. 503), a description is given of the differential analyser, and it is shown that the solutions of non-linear differential equations can be readily obtained by its use. Although it is possible to evaluate the solutions of such equations numerically and sometimes graphical methods can be employed, yet except for simple equations, numerical methods are laborious and lengthy, and graphical methods are limited in scope and accuracy and are also laborious to carry out on a large scale. The general idea of such a machine was due to Lord Kelvin. The practical realization of the idea is due to Dr. V. Bush, of the Massachusetts Institute of Technology, where the first machine of this kind was designed and constructed. A similar machine built by the Metropolitan-Vickers Electrical Co., Ltd., is installed at the University of Manchester and there is another at the University of Pennsylvania.

Immediately following the paper describing the

differential analyser, there is an excellent account of the practical application of it to study the transients on a distortionless transmission line, by Prof. Hartree and Dr. Porter. The ever-increasing volume of technical literature on lightning and its effects on transmission lines and terminal equipment provides evidence of the attention now being paid by engineers to this problem. It is now known that the severity of a transient occurring at a line terminal may be lessened by flattening the front of the wave, by means of wave modifiers or surge absorbers or by reducing its amplitude by means of 'arresters' of various types. The principal features of the majority of arresters of the 'spillover' type is that their action depends on the use of a material having a non-linear current-voltage characteristic.

This paper describes the solution of the problem of evaluating the history of a transient on a finite line with such a non-linear impedance at one or both ends. The behaviour of a transient on a finite distortionless line can be described in terms of two travelling-wave systems propagated in opposite directions along the line. The voltages in these two waves satisfy two ordinary differential equations depending on the terminal conditions, and involving a relation between the voltage at two times differing by the time of travel of a wave from one end of the line to the other and back. Equations of this type can be handled mechanically by means of the differential analyser, and the use of the differential analyser does not require that the terminal impedances should have linear characteristics. The authors apply the instrument to a line with a capacitance at one end and a non-linear resistance (lightning arrester) at the other. Specimens of machine solutions, both with a linear and a non-linear resistance at the far end, are given and discussed, and compared with oscillograms taken on an actual line.

Electric Power Supply in India

AT the annual meeting of the National Academy of Sciences, India, held on March 5, a symposium was arranged on the subject of India's power supply. In opening the discussion, Prof. M. N. Saha said that no subject could at the present moment be of greater importance than that of a cheap and abundant power supply. The whole industrial efficiency of a nation depends on it. He pointed out that there are countries in the world that have developed all their power resources—Norway, United States, England and Germany; but India, China and Abyssinia are still dependent on a medieval economy. In Norway, the total output per head per annum is nearly 1,800 units. In England and Germany the power is mainly derived from coal, but the output per head is probably nearly the same. In India the output cannot exceed 90 units, of which about 60 is from human labour, 10 from animal power and 20 from steam and electrical power combined.

If the problems of poverty and unemployment in India are to be solved, the power resources of the country must be organized so as to bring them to the level of Europe, America and Japan. Dr. Tandon said that the sponsors of the Ganges canal project would have done better service to the country if, instead of trying to capture the public imagination by the ideal of rural electrification, they had concentrated the load near the generating stations for the development of the heavy chemical industries.

Pandit J. Nehru, in summing up the discussion, said that everyone saw the necessity of establishing a power research and survey institute. But democratic Governments are greatly burdened by their ordinary routine work, and complaints from innumerable persons who now have access to them. The first things they do are naturally those demanded by hundreds of thousands of people, and so they have no time to listen to the counsels of a few dozen, however great their reputation may be. The expert man of science is not always a helpful person. He does not realize that things which have to be put before the Government must be definite and that the proposals must fit in with the realities of the situation. He asked the Academy to draw up definite proposals for benefitting the nation, and not vague aspirations as to what should or might be done.

At a subsequent meeting on March 29, Prof. Saha moved a series of resolutions which were unanimously carried. The Government is requested to appoint a committee of legal and scientific experts, and representatives of industry, to study the present Electricity Act and to recommend the necessary legislation required to nationalize the generation and distribution of electricity with the view of making the supply of electrical power in the country cheap and abundant. The second resolution requests the Government to select a body of graduates in physics and electrical and chemical engineering, and to send them to study the methods adopted in countries such as England, the U.S.S.R. and Switzerland. The third resolution is a request that a permanent body called the "Power Survey and Research Institute" be appointed. Finally, the National Academy noted with regret that the Government of the United Provinces, when appointing an Electricity Committee, did not consider it necessary to ask the Academy to nominate a specialist to serve on the Committee.

Science News a Century Ago

Invention of Daguerrotype

ON January 7, 1839, Arago described to the Paris Academy of Sciences the invention of Louis Jacques Mande Daguerre (1789–1851) for the photographic process of taking pictures on metal plates. Writing from Paris, a correspondent of the *Athenaeum* said, "So universal an interest was excited here by the paper read by M. Arago, that I called on M. Daguerre to possess myself, as far as was permissible, of the facts of this very extraordinary discovery. . . . Of course, I can as yet give no precise details as M. Daguerre naturally objects to impart them to anyone, till he has received definite answer from the Government, with whom he is in treaty for the sale of his secret. I should add that the discovery is authenticated past the power of question by the testimonials of such men as Biot, von Humboldt and M. Arago. His earlier sketches of four years ago have a slight haziness; some of his last works have the force of Rembrandt's etchings." Of the various subjects of Daguerre pictures, the correspondent mentioned the Quays of Paris, the Louvre and Notre Dame, the picture of the last having been taken in the rain.

Daguerre had begun life as an inland revenue officer, then became a stage painter, and in 1822, in conjunction with M. Bouton, opened the Diorama in Paris, which for seventeen years was a great attraction. For many years he endeavoured to produce permanent pictures by the action of sunlight, and collaborated with Nicéphore Niepce (1765–1833). Daguerre's pictures were produced on plates of silver covered with a film of iodide. After exposure, the plates were developed by means of mercury vapour and fixed in a bath of hyposulphite of soda.

Parallax of α Centauri

ON January 9, 1839, the discovery of the parallax of α Centauri was communicated to the Royal Astronomical Society by Thomas Henderson (1798–1844), the first Astronomer Royal for Scotland, to which office he had been appointed in 1834, a year after his return from the Cape of Good Hope. "With a view," said Miss Clerke, "to correcting the declination of the lustrous double star α Centauri . . . he effected a number of successive determinations of its position, and on being informed of its very considerable proper motion ($3.6''$) annually he resolved to examine the observations already made for possible traces of parallactic displacement. This was done on his return to Scotland. . . . From the declination measurements made at the Cape and duly reduced, a parallax of about one second of arc clearly emerged . . . but, by perhaps an excess of caution, was withheld from publication until fuller certainty was afforded by the concurrent testimony of Lieutenant Meadows' determinations of the same star's right ascension. When at last, January 9, 1839, Henderson communicated his discovery to the Astronomical Society, he could no longer claim the priority which was his due. Bessel had anticipated him with the parallax of 61 Cygni by just two months."

William MacMichael (1784–1839)

DR. WILLIAM MACMICHAEL, an eminent London physician, who died on January 10, 1839, was born at Bridgnorth in Shropshire in 1784, the son of a

banker. He was educated at the local grammar school and Christ Church, Oxford, where he qualified in 1808. Appointed Radcliffe travelling fellow in 1811, he visited Russia, Turkey, the Balkan States and Palestine, and in 1817 and 1818 recorded his experiences of the journey. In 1818 he settled in London and four years later was appointed physician to the Middlesex Hospital. In 1829 he was made physician extraordinary to the King. At the Royal College of Physicians, of which he was elected fellow in 1818, he held the office of censor in 1822 and 1832 and of registrar in 1824. MacMichael is best known as the author of "The Gold Headed Cane" which was published anonymously in 1827 and contained the lives of Radcliffe, Mead, Askew, Pitcairn and Baillie, the successive owners of the cane, now in possession of the Royal College of Physicians. He was also the author of "Lives of British Physicians" (1830), also published anonymously and written in the same delightful style as the previous work, as well as of unimportant books on scarlet fever (1822) and cholera (1831).

Magnetical Observations

In its report of the meeting of the Royal Society held on January 10, 1939, the *Athenaeum* included the report to the Council by the Joint Committee of Physics and Meteorology appointed to consider the propriety of recommending the establishment of fixed magnetic observatories and the equipment of a naval expedition for observations in the Antarctic. The report, signed by Sir John Herschel, was approved, and Herschel, together with Sabine and Wheatstone, were requested to wait on Lord Melbourne. After reading the report, Lord Melbourne stated that he would urge Her Majesty's Government to adopt measures for carrying the resolution of the Council into immediate effect.

University Events

CAMBRIDGE.—The International Wool Publicity and Research Secretariat is supporting in the University a research studentship at the School of Biochemistry, and on the conclusion of the present holder's tenure it will consider providing for a further tenure appointment to which will be made by the University. The present holder is R. L. M. Synge, of Trinity College.

L. C. Young, of Trinity College, has been approved for the degree of Sc.D.

Dr. W. Feldberg has been appointed University lecturer in physiology.

The subject proposed for the Adams Prize for the period 1939-40 is "The Theory of Numbers". This phrase may be interpreted in the widest sense and as including, for example, the additive, algebraic, analytic and geometric theories.

READING.—Prof. F. J. Cole, professor of zoology since 1908, is resigning from the chair in September. Prof. Cole's researches have dealt chiefly with comparative anatomy and the history of zoology. From 1895 until 1906 he was lecturer in zoology in the University of Liverpool.

Societies and Academies

London

Royal Society (Proc., A, 169, 1-148; 1938).

SIR WILLIAM BRAGG: Presidential address.

J. L. LIXIUS and A. J. ALLMAND: The simultaneous sorption of carbon bisulphide and water vapour by activated charcoals.

R. F. BARROW and W. JEVONS: The band spectrum of silicon monosulphide and its relation to the band spectra of similar molecules.

R. W. SILLARS: The behaviour of polar molecules in solid paraffin wax.

J. SAYERS: Ionic recombination in air.

P. WEISS: (1) On the Hamilton-Jacobi theory and quantization of a dynamical continuum. (2) On the Hamilton-Jacobi theory and quantization of generalized electrodynamics.

E. A. GÜGGENHEIM: The statistical mechanics of co-operative assemblies.

Edinburgh

Royal Society of Edinburgh, December 5.

A. R. GLEN: The Oxford University Arctic Expedition to North East Land, 1935-1936. The north coast of the island was mapped in detail, while reconnaissance surveys were made of the east and south coasts. The ionosphere research carried off at the base in Brandy Bay yielded results of considerable value to the further development of world wireless communications, while measurements of the atmospheric ozone and observations on the aurora were successfully made. The geology and biology of North East Land were studied in some detail. Finally, at two stations established on the inland ice a comprehensive programme of glaciological and meteorological research was completed.

VERA FREYER: Structure and function of the alimentary canal of some tectibranch molluscs, with a note on excretion. The morphology, minute structure and functioning of the gut of four species of tectibranch molluscs has been described. Food, sensed by cephalic sense organs and raked in by the radula, is crushed by calcareous plates in the gizzard and exposed to enzymes from the salivary and digestive glands. Digestion of carbohydrates, proteins and fats occurs, soluble products and minute particles being passed through the stomach to the liver for absorption and further digestion. Indigestible food from the digestive gland is excreted via the anus and the kidney in different proportions in bivalves and gastropods.

MRS. E. M. BEATTIE: Investigation of visual threshold values. The main object of the work was the determination of the effect of fatigue, under certain conditions, on the magnitude of the threshold value. The time of fatigue by a light of given intensity was varied, and it was found that the apparent intensity, as measured by the critical frequency of flicker, of another light, also of constant intensity, was markedly increased by increase of the time of fatigue. The same condition holds when an interval of time elapses between the cessation of fatigue and observation of the second light, but the effect is smaller.

Paris

Academy of Sciences (*C.R.*, 207, 1137-1268, Dec. 12, 1938).

G. BERTRAND: Quantity of zinc in sea water. Samples of water off the coasts of France and of the Dead Sea have been examined by a chemical method (determination as calcium zincate); the figures obtained are 3-4 mgm. and 4.37 mgm. zinc per litre respectively.

L. BLARINGHEM and K. C. CHIN: New cases of xenia in wheat hybrids (*Triticum monochorum*, *T. aestivum* and *T. vulgare*).

E. ROUBAUD, J. COLAS-BELOUVE and G. J. STEFANOPOULO: Behaviour of yellow fever virus in the mosquito *Aedes geniculatus*. Transmission of the fever occurs when the mosquitoes are kept at 30-35° C., but not when they are at 20-22° C.

V. VOLTERBA and V. A. KOSTIZIN: Remarks on the toxic action of the medium, *à propos* a note by M. Regnier and Mlle. Lambin [Development of *Staphylococcus aureus* and *Bacillus coli* in a liquid medium].

P. LEJAY: Gravimetric map of the Philippines.

P. LÉVY: Brownian movement and geometric schemes.

O. PAUC: Contribution to the problem of M. Fréchet relating to the investigation of a derivable parametrization for curves with a tangent at every point.

M. BRELOT: Closed ensembles.

A. DVOŘÁK: Semi-convergence of series, and in particular of Dirichlet series.

M. GODEFROY and H. PONCIN: The idea of stability.

A. FOCH and G. CHASTINE: Chromo-photography and gyrotory flow.

V. VOLKOVICH: Some properties of vertical trajectories in plane problems of convection.

L. MALAVARD: Correction of air-flow for an elliptic channel.

J. SOLOMON: Quantum theory of gravitation.

J. GÉHÉNIAT: Wave mechanics of the heavy electron.

N. CARRERA: Perturbation of a problem of proper values by deformation of the boundary.

J. ROUBAUD-VALETTE: Certain equations representing a photon.

Mme. M.-A. TONNELAT: Relations between the theory of the photon and the theory of the heavy electron.

A. PROCA: A symbolic equation combining the equations of the mesotron (heavy electron), those of Kemmer, of Klein-Gordon and the L. de Broglie equations of the photon.

O. SALCHAND: Experimental arrangements for measuring the velocity of sound in liquids by a resonance method: measurement of the velocity of sound in mercury. The mean velocity at 22.5° C. found was 1,407 m./sec.

L. TISZA: Viscosity of liquid helium and the Bose-Einstein statistics.

T. BOGGIO: Movement of an electrified particle in an electric field and in a superposed magnetic field.

Y. ROCARD: Weakening of the electromagnetic fields on ultra-short waves at river crossings. Such local effects may give useful information to aircraft.

M. LEMARCHANDS and W. JUDA: Discussion of the phenomena of electrolytic rustion.

(To be continued.)

Rome

National Academy of the Lincei (*Atti*, 27, 471-492; 1938).

G. GHERARDI: Construction of equivalence series on a reducible algebraic curve.

O. CATTANEO: Contact of two elastic bodies: local distribution of the forces (3).

A. ALIBRANDI: New experimental confirmation of the necessary participation of the inborn afferent path in the mechanism of conditioned reflexes.

G. ARAGONA: New observations on the blood-sugar raising pancreatic hormone of G. Martino.

V. CAPRABO: pH value of the content of the seminal vesicles of the albino rat.

V. ZAGAMI: Experimental researches on the seminal fluid. (3) Variation of the pH of the human fluid with temperature and dilution.

Atti, 27, 493-603; 1938.

F. ENRIQUES: Characteristic properties of irregular algebraic surfaces.

U. BARBIERI: Geodetic-astronomical station erected on the trigonometric vertex of Montecastello near Alessandria in August 1934.

G. QUAGLIARIELLO and F. CHIDRANGOLO: Solubility of fatty acids and of glycerides in bile and in bile salts.

A. STELLA: New studies on the tin deposit of Campiglia.

J. C. VIGNAUX: Polygenic functions of one and of several dual complex variables and of bidual variables (1).

E. FROLA: Cauchy's problem and equations with linear partial derivatives having constant coefficients.

G. N. WATSON: Tabulation of a particular function defined by an improper integral.

T. BOGGIO: Solutions of a system of equations with partial derivatives.

O. CHISINI: A more general theory of the existence of multiple planes.

G. C. MOISIL: Geometrical considerations of the integration method of Hadamard-Théodoresco (1).

A. CARRAS: Resolution of a problem relating to the perturbations imposed on continuous systems.

G. LAMPARELLO: Stationary motions in the dynamic problems of Liouville.

O. ZANABONI: Possibility of neglecting the work due to the deformation of the cutting surface and of the axial force in comparison with that of the moments.

G. L. ANDRISCI: Solar radiation at Rome from 1933 until 1936.

G. WATAGHIN: A system of gravitational equations of the first order (2).

G. GIACOMELLO: Structure of some triterpenes.

C. PERRIER and E. SEGRÈ: Some chemical properties of element 43 (2).

R. PIONTELLI: Influence of ultra-sonics on discharge potentials of hydrogen, oxygen and chlorine.

A. CAVINATO: The Permian in the Orroli territory (Sardinia).

S. DOZZI DI DELUPIS: Phenomena of activation in plant growth (1).

G. GONDANICH: New observations on the drying of shoots of poplars.

A. ALIBRANDI: Efficacy of the spoken word in producing the conditioned reflex of blinking in dogs.

V. ZAGAMI: Experimental researches on the seminal fluid (4). pH value of dog's seminal fluid.

Forthcoming Events

Tuesday, January 10

PHARMACEUTICAL SOCIETY, at 8.30.—Prof. J. H. Gaddum: "Recent Discoveries about Animal Hormones".

Friday, January 13

PHYSICAL SOCIETY, at 5.15—Sir Ambrose Fleming, F.R.S.: "Physics and Physicists of the Eighteen-seventies".

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned

ASSISTANT LECTURER IN ELECTRICAL ENGINEERING in University College, London—The Secretary (January 14).

UNIVERSITY READER IN METEOROLOGY in the Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, W.C.1 (January 20).

UNIVERSITY READER IN BIOCHEMISTRY in Guy's Hospital Medical School—The Academic Registrar, University of London, Senate House, W.C.1 (February 1).

CHEMIST in the Institute for Medical Research, Federated Malay States—The Director of Recruitment (Colonial Service), 8 Buckingham Gate, London, S.W.1 (February 10).

ASSISTANT PROFESSOR OF PHYSICAL AND GENERAL CHEMISTRY and ASSISTANT PROFESSOR OF MINERAL AND INORGANIC CHEMISTRY in the Indian Institute of Science, Bangalore, India—The Registrar (February 16).

ASSISTANT ADVISORY OFFICER to the Board of Greenkeeping Research—The Director, St. Ives Research Station, Bingley, Yorks.

DIRECTOR OF RESEARCH to the Research Association of British Flour-Millers—The Secretary at 40 Trinity Square, London, E.C.3.

BACTERIOLOGIST in the Research Laboratory of the Royal College of Physicians of Edinburgh—The Secretary, Royal College of Physicians, Edinburgh, 2.

SUPERCONDUCTIVITY

23 text-figures

By D. SHOENBERG

6s. net

The classic experiment of Meissner and Ochsenfeld a few years ago led to considerable revision of the phenomenological aspect of Superconductivity, and showed serious flaws in its theory. Recent developments, though they have not materially altered this position, have at least made possible a coherent statement of what it is that the theory has to explain. This statement is set out in the present survey.

UNIVERSITY PRESS*in the Service of Science*

The highly-specialized photographic needs of astronomy, spectroscopy and micrography receive constant attention in the Kodak Research Laboratory at Welldstone—one of the best equipped of its kind in the world. A wide range of plates can be supplied for scientific purposes, and Kodak technicians are always ready to consider the preparation of special plates to meet individual needs. All scientists who use photography as an aid to investigation are invited to send details of their requirements to Mr. N. Alfred, Dept. 6,

Intellectual Co-operation between the Nations

WE live and move and have our being in a world of contradictions—in a world which has shrunk in its dimensions to an almost incredible extent during the last generation. America and the Antipodes are but a few days' journey from Europe; wireless can put a girdle round the globe in a time undreamt of by Puck; the concerted labours of the physicist, the engineer, and the biologist have made it possible to transport perishable produce on a large scale from country to country—produce which adds in a high degree to the amenities of life in our community. All these results have been achieved by thought and labour which were truly international in character.

The fundamental problems of life, of art and of ordered knowledge know neither racial nor geographical boundaries. Grant that we have reached a certain stage in our gropings into the infinite, then, within those limits, the message of Plato and of Confucius, of Dante and of Wordsworth, of Beethoven and of Brahms, of Newton and of Einstein, are for all ages and all climes. Unless man is free in thought, and free in the expression of his thoughts, the wisdom of the past and of the present is of small avail for the increase of the happiness of the human race; and it is a bitter comment on the trend of our modern civilization that men should be turning to the noble words of the Areopagitica as expressing beliefs still to be fought for, not as truths for ever demonstrated by the struggles and aspirations of centuries past and gone.

"As good almost kill a man as kill a good book; who kills a man kills a reasonable creature, God's image; but he who destroys a good book, kills

reason itself, kills the image of God, as it were, in the eye. . . . We should be wary, therefore, what persecution we raise against the living labours of public men, how we spill that seasoned life of man, preserved and stored up in books; since we see a kind of homicide may be thus committed, sometimes a martyrdom; and if it extend to the whole impression, a kind of massacre, whereof the execution ends not in the slaying of an elemental life, but strikes at the ethereal and fifth essence, the breath of reason itself; slays an immortality rather than a life." How would these immortal words have struck our ears in the freer air of a generation ago? How do they read to-day?

We have said that we live in a world of contradictions, for, though the gifts of science have brought the nations closer in space and in time than ever before in the history of civilization, yet, paradoxically enough, man stultifies the effects of these benefits in countless ways. He erects economic barriers between the nations; he exacerbates national disagreements, visualizing the exchange of commodities, on which our mutual prosperity depends, as a process of warfare; he produces want and misery in a world which, wisely ordered, could go far in using the gifts which scientific advance is providing, to supply the material needs of all.

All the more reason, then, to welcome any national pronouncement which emphasizes the spirit of co-operation rather than that of cut-throat competition, and such a pronouncement is doubly welcome when it is concerned with the fostering of general cultural relations between a great democracy and the other countries of the

world. • The order recently signed by Mr. Cordell Hull, the Secretary of State in President Roosevelt's Government, establishing in the Department of State a Division of Cultural Relations, is of great significance. In a civilization where knowledge is increasing, where values are changing, at a rate never before dreamt of, and in which almost every possible element of instability is present, no opportunity should be lost for bringing together nationals of all countries to discuss, amicably and fraternally, problems which are the concern of all, and few better meeting grounds could be chosen than those which are provided for the encouragement and strengthening of cultural relations. Individual attempts to institute such contacts have been many and have been attended with varying degrees of success, or failure, but Governments are slow to take such action, and Mr. Cordell Hull's order marks an important step in advance, and provides an example that may well be followed by other Governments as a most weighty means of diminishing the tensions, and alleviating those differences which, unhappily, are such a prominent feature in international relations to-day. The order, which takes effect as from July 1938, has scarcely, as yet, received the notice which its importance merits. The significant part of the text, as published in the issue of *Science* of November 25, 1938, runs :

For the purpose of encouraging and strengthening cultural relations and intellectual co-operation between the United States and other countries, it is hereby ordered that there shall be established in the Department of State a Division of Cultural Relations.

The division will have general charge of official international activities of this department with respect to cultural relations, embracing the exchange of professors, teachers and students; co-operation in the field of music, art, literature and other intellectual and cultural attainments; the formulation and distribution of libraries of representative works of the United States and suitable translations thereof; the preparations for and management of the participation by this government in international expositions in this field; supervision of participation by this government in international radio broadcasts; encouragement of a closer relationship between unofficial organizations of this and of foreign governments engaged in cultural and intellectual activities, and, generally, the dissemination abroad of the representative intellectual and cultural works of the United States and the improvement and broadening of the scope of our cultural relations with other countries.

In fulfilling its functions, the Division of Cultural Relations will direct the conduct of exhaustive studies and have responsibility for the elaboration and the carrying into effect of a comprehensive and co-ordinated plan of activity in this country for the

strengthening of international intellectual and cultural relations; it will assist in the preparation and interpretation of treaties in this field; it will supervise the formulation of regulations and procedure necessary for the fulfilment of obligations under the Convention for the Promotion of Inter-American Cultural Relations and other treaties and conventions relating to cultural relations to which the United States may become a party; it will draft or review correspondence with foreign governments, American diplomatic and consular officers and all other correspondence pertaining to these activities; it will collaborate with the Office of Education and other government departments and agencies, the National Committee on Inter-American Intellectual Co-operation, other educational and cultural organizations and institutions and foreign missions in Washington.

The Division of Cultural Relations will function under the general supervision of the Under Secretary of State and in close co-operation with the geographical divisions.

It will be noted that science receives no overt mention, but it is to be presumed that scientific advances and the implications of such advances will receive full consideration under some of the more general heads of the order.

Official action in democratic communities is apt to follow, rather than to lead public opinion, save in exceptional instances, but Mr. Cordell Hull's order synchronizes with other movements which have already been discussed in the columns of *NATURE*. The British and American Associations for the Advancement of Science, in their arrangements for an exchange, in alternate years, of lecturers to deliver at the meetings of the Associations addresses which shall, broadly speaking, be conceived on the lines of presidential addresses, have initiated a movement which will undoubtedly have far-reaching effects; and this movement is further assisted by the decision of the Associations to keep officials of each Association intimately acquainted with the details of the proceedings of their respective bodies. It is good to know that the Government of the United States of America regards these decisions as having sufficient importance to warrant their forming part of a wider national policy, and such recognition inspires the hope that other countries will participate in this movement for the encouragement of international cultural relations.

The structure of our civilization is cracking; if it is to be saved at all—and, imperfect though it may be, it is worth conserving and developing—it can only be saved by the encouragement of those movements which stress the urgent need for international co-operation and understanding.

The Colonial Service in the British Empire

The Colonial Empire and its Civil Service
By Charles Jeffries. Pp. xxv + 259. (Cambridge:
At the University Press, 1938.) 10s. 6d. net.

THIS book, as explained by Lord Harlech in his introduction, is an "attempt to tell, as straightforwardly and simply as possible, the story of the development of the British Colonial service". The author has had a difficult task, but has succeeded admirably in condensing into the pages of a comparatively small volume an immense amount of matter that concerns the Colonial Service.

His Majesty's Colonial Service of a hundred years ago dealt with regions that are now no longer under its control. In these days, the great Dominions have their own separate form of administration and although the island Colonies, such as those in the West Indies and Mauritius, and the West African Colonies of Sierra Leone and the Gambia do indeed appear on the old list, others such as Malaya, Nigeria, the Gold Coast and the East African territories were not then parts of the Empire. The chapter on the early history of the Service indeed affords fascinating reading and gives one a clear idea of the way in which the Colonial Empire has grown and how many changes have had to be made to meet its expanding needs. One cannot help feeling that in those early days the territories which now form the Colonial Empire were the Cinderellas to what are now the Dominions. These were larger and more vociferous in their demands and had developed far more rapidly than the smaller Colonies.

Matters have changed since the Dominion Office was formed in 1925, and we read of the remarkable way in which the Colonial Service proper has been strengthened and re-organized since the Great War. The time was evidently ripe, for a perusal of these pages enables one to realize in what a haphazard, not to say casual, manner the Colonial Empire of Great Britain has grown up. The laws and regulations even now differ in a remarkable way between territories often adjacent, and it was presumably to counter the parochial attitude that was (and still is) so often exhibited by individual Colonies that the wide reforms of the post-War period were instituted. The Great War had indeed brought to light many glaring defects in our organization, more particularly perhaps in the failure to develop fully the natural resources of the Colonies, and the public health and education of the natives. As an example of the new outlook, one may instance the reports of the Lovat Com-

mittee in 1927 and 1928, which made recommendations on agricultural research and administration in the non-self-governing Dependencies and also suggested the institution of one service for all the Colonies. Its proposals, after implementation, have done much to develop the agricultural, forestry and other technical services.

The Warren Fisher Committee followed with further recommendations, and this led to the decision of the Secretary of State to form a unified Colonial Service in 1930. Subsequent developments recognized the existence of a single Imperial Colonial Service. Within this, branch services have been organized on a professional and not on a regional basis. Thus we now have Colonial administrative, legal, medical, agricultural services, and so on, each having a technical adviser in the Colonial Office itself. A further step was to lay down that members of these unified services would normally be recruited from outside the Colony itself. This, as is explained, "left room for the fullest scope to be allowed to each Colony to develop its public service in the best way suited to its local conditions". There is little doubt that the unification of the service has done much to increase the prestige and sense of *esprit de corps* among its members, a point that has been ably brought out by the author. The clarification of the proposals regarding recruitment has also had the effect of attracting a number of desirable recruits from the universities.

Difficulties in the strict application of these ideals naturally occur, since the Colonies differ from each other in so many ways: Disappointment may be felt when the Colonial Office feels it expedient to give way to a local Government in the matter of filling some post locally instead of by an appointment from the unified Colonial Service. These difficulties are always likely to crop up from time to time in communities that are in the process of developing a political self-consciousness. Again, much remains to be done in levelling up the anomalies that undoubtedly exist between various Colonies in respect of salaries, housing, leave passages, and so on. This matter needs urgent attention, as unless it is equitably settled one suspects that certain Colonies will acquire a reputation that will render them unpopular to the serving officer and this will lead to an inevitable deterioration in the standard of work.

The subdivision of the unified Colonial Service into separate technical services has many points in its favour. It is to be hoped, however, that these

sub-services will not become too water-tight. The closest co-operation between all officers is needed to solve many of the pressing problems, and indeed their solution is almost always a matter of teamwork. The higher posts in the Service should be open to every member, whether he be a specialist or an administrative officer, for it is ability and

personality that count, and the wider the net is spread the more likely is the right man to be found.

The book is to be commended to all who are in any way interested in colonial questions, as it gives a complete history of the Colonial Service from its very early days to the present time.

G. E.

The Mechanism of the Egg

Embryonic Development and Induction

By Prof. Hans Spemann. (Yale University: Mrs. Hepsa Ely Silliman Memorial Lectures.) Pp. xii+401. (New Haven: Yale University Press; London: Oxford University Press, 1938.) 22s. 6d. net.

AT last we have the pleasure of welcoming the largest work so far written by one who is perhaps the greatest living master of experimental morphology. It has received admirable treatment by the Yale University Press; the clear printing aids the reader's eye, and the matt paper does justice to every nerve-cell in the numerous illustrations.

It was Gustav Born who long ago discovered the remarkable healing power of amphibian embryos, and the manner in which they can be operated upon with very fine glass needles, hair-loops, and other delicate instruments. Under the dissecting microscope the tissues cut cleanly "like a mixture of cheese and cotton-wool" and the methods permit, of course, of that fundamental requirement of experimental morphology, namely, the transplantation of pieces or regions of one embryo into another, that is, into an abnormal but living environment. It may then be seen whether they follow their previous course of development, or whether they fall into step, as it were, with their new environment, and go along with it to whatever its destiny may be in the finished embryo.

Born did not carry the experiments far. It was Hans Spemann who, in a "Gedankengang" extending over thirty years, analysed, with various collaborators, the process of determination in the amphibian embryo. With Hilde Mangold in 1924 he discovered the primary organization-centre (organizer), in the dorsal lip of the blastopore, which determines the main axis of the vertebrate embryo, that is to say, the neural tube, notochord and somites.

The present book, after a short historical discussion of some of the ideas current in earlier days of embryology, begins with a detailed account, not of this 'primary organizer' just now mentioned, but of the 'secondary organizer' which works on

the ectoderm to produce the lens of the eye, when the eye-cup grows out towards the skin from the forward end of the nerve-tube. At first sight, this way of introducing the subject of organizer phenomena may seem to have more disadvantages than benefits, for the processes of lens-induction vary a good deal as between different species of amphibia. Yet this very fact allows of a special insight into the relation of stimulus and response in organizer action. In some amphibia, the skin is absolutely incapable of producing a lens without the stimulus from the eye-cup, but in others it produces a more or less good lens if the eye-cup stimulus is not allowed to act. Hence the concept of 'double assurance' derived from engineering. If one mechanism should fail in the normal course of development, another appears in reserve. It is not yet clear, however, whether the second process only comes into play if the first is inhibited, or whether both processes work together in the same direction in normal development as a "kombinative Einheitsleistung". In any event the question does not arise so acutely with regard to the primary organizer.

The next series of chapters is devoted to the state of affairs in the gastrula during the working of the primary organizer. Spemann deals in turn with tests of potencies, inductions of secondary (twin) embryos by normal organizers and by abnormal media, such as dead tissues of adult organisms, or by chemical preparations. Although his account of the morphological problems has all the brilliance which we expected, the same can scarcely be said of those sections dealing with the biochemical aspects of the phenomena. It is a striking exercise in the psychology of science to observe how his assured touch deserts him when he appraises chemical evidence and chemical arguments. Thus he does not appreciate the importance of Holtfreter's discovery that on heat-coagulation (or other protein denaturation), tissues such as ventral ectoderm, which do not normally possess inductive power, acquire it, although he himself says (p. 232) that the "substance is then either produced anew, or *set free* by suitable treatment" (*italics mine*).

He does not see that the ventral ectoderm, in which the substance may be set free, is precisely the same thing as the presumptive epidermis, on which organizer activity has perforce to be tested. He does not therefore distinguish between implants which do injury to the tissue and so liberate the tissue's own organizer-substance, and those which act in minute concentrations, and are hence less likely to liberate it. He thus gives up too easily the search for logical consistency in the chemical facts, and takes refuge in a facile writing off of the whole effect as probably "unspecific".

What puzzles the reader most, however, is the kind of assumption which Spemann regards as self-evident. Thus on pp. 220 and 370, where he is discussing the induction of eyes and lenses after implantation of adult heart, he says, "One thing is evident from the beginning, that a cooked heart, for instance, which induced an isolated lens, cannot have brought about this effect by some specific lens-forming agency". Now the evidence that the primary organizer involves a chemical substance is accepted by everyone. Since all adult tissues act, the simplest assumption is that they all contain the substance, capacity to react to it having long been lost. If they contain the primary organizer, why not various secondary organizers? There is at any rate no lack of chemical compounds present in cells for which no function has yet been found. So why is it self-evident that heart tissue cannot contain secondary lens-organizer substance?

There are two places where the characteristics of the morphologist's outlook appear with special force. Thus on p. 242 Spemann says, "The altered metabolism in the dorsal lip of the blastopore is, surely at first, a consequence of the induction, not its cause". This is strikingly reminiscent of Liebig's view which called forth from Traube in the early days of the study of yeast fermentation the famous remark: "Der Chemie vermag wohl die physiologische Tatsachen, aber nicht der Physiologie die chemische, erklären". Or again, on p. 245, Spemann asks how "structure can be produced by a factor which, like a chemical substance, lacks structure in itself, in the morphological sense of the word?" Surely the whole of organic chemistry is, in a real sense of the word, a realm of structure. With molecules of the complexity of proteins, we need surely have no excessive intellectual difficulty in picturing a relation between morphological differences and chemical differences, even though as yet we have no detailed knowledge of the manner in which this occurs. On the other hand, no book could show better than this one the beauty of the analysis of biological phenomena which can be accomplished by the morphological mind. Around p. 354, for example, the results of exposing the

ectoderm of different species to the action of the same organizer is discussed. The ectoderm reacts, but it gives the answer, as it were, in its own language. Stimulated to form a balancer, it does so, but it makes one like embryos of its own species, and not like that of its host. Stimulated to form mouth parts, it forms teeth or horny jaws as the case may be, irrespective of which of these formations is characteristic of its host. The 'cue', says Spemann, therefore, is rather vague; the ectoderm reacts, but in its own way, according to the tradition of its species.

In later chapters, Spemann considers the gradient theory of Child from a critical point of view. Some may feel that he displays an almost too excessive aversion from gradients. We may grant that the claim of Child to show that gradients are gradients of respiratory rate has never been substantiated. But not a few writers have found the concept of gradient useful, and indeed if the diffusion of a chemical substance takes place from a point in space, as may well happen in the case of the primary organizer, a gradient system must be formed. Even a differential supply of nutrient substances in the ovary as a factor in polarity is objected to (p. 325). The fundamental trouble is stated on p. 331: "It is hard to understand how qualitative differences may arise from quantitative ones in different regions". That depends on one's philosophy. There are philosophers who have found the transformation of quantity into quality a fundamental property of Nature, observable in many fields besides embryology, as in the classical instance of the increasing length of the paraffin chain.

In the conclusion, Spemann justifiably says that the more exact our knowledge becomes about the chemical substances involved, the more the burden of explanation is thrown back on the reactivity, the competence, of the tissues affected by them (p. 369). He even writes, "the very conception of the organizer became problematical". It is to be hoped that this will not cause misunderstanding. The facts of organizer action have been demonstrated again and again. Organizer phenomena involve the action of 'morphogenetic hormones', and their importance is that for the first time they bring home to us how closely bound up normal morphogenesis is with normal embryonic metabolism.

This is a great book. But it is not a book to be read uncritically. The best way in which we can render homage to one who is perhaps the last great representative of that "reine deutsche Wissenschaft—Entwicklungsmechanik", is to read and re-read him, framing new hypotheses, which may or may not be better than his, for his perdurable facts.

JOSEPH NEEDHAM.

History of Cambridgeshire

The Victoria History of the County of Cambridgeshire and the Isle of Ely

Edited by L. F. Salzman. (The Victoria History of the Counties of England.) (Published for the University of London Institute of Historical Research.) Vol. 1. Pp. xiii + 436 + 21 plates. (London: Oxford University Press, 1938.) 63s. net.

IT may seem a matter for surprise that Cambridgeshire, a county in which is a great centre of learning, should have had to wait so long for the first volume of its Victoria History. The delay is the reader's gain. Most of the chapters in this volume, but more especially those dealing with geology—at least as regards the quaternary deposits—botany, and archaeology could not have been written a generation ago, when publication of the County Histories began, as they appear here. This is not entirely a matter of fresh evidence, though this plays its part; but new methods of investigation and interpretation have remoulded the reconstruction of prehistory, while a new orientation has broadened, and at the same time intensified, the study of the environmental conditions and culture of early man. For this we are largely indebted to the geographico-archaeological studies of the Cambridge region by Sir Cyril Fox in the period immediately following the Great War, and the later studies of the Fenland Research Committee, to which the investigation of the formation of the peats of the Fenland has contributed not a little.

The first volume of the Cambridgeshire series follows the general plan of the History as a whole. It deals with the natural conditions, the geology, botany, and zoology of the county, and with the evidence of human occupation in prehistoric and Saxon times, ending with the Domesday record. In the last named the county is peculiarly fortunate in the survival of three independent records of the land tenures of the period.

Although the geological structure of the county is simple, being divided between Jurassic and Cretaceous, the surface, although nowhere greatly elevated, is sufficiently varied. The feature which gives the county its special interest is the fenland and its influence on the fauna and flora. Although the fenland has been drained, Wicken Fen survives for the study of former conditions; but as is shown by the chapter on botany by Dr. H. Godwin and those dealing with the zoology under its several divisions, many rare and interesting species have vanished. Among these are the avoget

and the ruff as breeding species and the great bustard; while the county was probably the last haunt of the large copper butterfly and, it may be, the polecat. The oldest specimen of the *P. daplidice* butterfly, now in the Oxford entomological collection, was caught here in the last decade of the seventeenth century; and the swallow-tail, *P. machaon*, rare in Britain, still survives.

Cambridgeshire, however, is in a marked degree a marginal area; and it is noticeable how in the discussion of numerous questions a crucial piece of evidence is drawn from areas at varying distances outside the county border. This point especially is to be noted in connexion with the quaternary deposits and their relation to the history of early man, here considered in the revised studies of the late Dr. J. E. Marr, which show the county as marginal to the great East Anglian area, while in the later periods Dr. Clark's analysis of culture indicates how it bears a like relation, now to the south and south-west, now to the cultural spread, which can, as a rule, be traced to the Wash.

In the chapter on early man, for which Dr. J. G. D. Clark is responsible, the palaeolithic period is represented by the records of a number of finds, extending from the Challeian to the close of the period; but on the whole the showing is poor. This, as the author indicates, is due to a lack of systematic investigation, rather than proof positive that palaeolithic man did not spread to this area from the East Anglian region. In the earlier chapter on geology, it pointed out that Cambridgeshire offers a poor field for observation, owing to the closing down of the industrial undertakings upon which the geologist has to rely for his opportunities; and the same applies to observations of the earliest periods of prehistory, when funds are not available for specific investigations. Incidentally, it may be pointed out that in both the Iron Age and in the Saxon period, with which Mr. T. C. Lethbridge deals, much valuable information was undoubtedly lost through the development of the sites at the St. John's cricket ground, Grange Road, and at Girton in the eighties of the last century, when archaeological knowledge and method were immature.

From mesolithic times onward, much evidence has come from research within the county area, and is still accruing, which is of great value in the study of the character, succession, and chronology of prehistoric cultures. For this, as already mentioned, thanks are due to the Fenland Research Committee, for which Dr. J. G. D. Clark himself

has to no small extent been responsible. The application of the methods of pollen analysis to the peat deposits, it is true, has not as yet produced the results which were anticipated; nevertheless, the investigations at Plantation and Peacock's farms, Shippea Hill, to which frequent reference is made here, have provided an illuminating and unique sequence from Tardenoisian to Early Bronze Age, and demonstrated their relation to the marine deposits laid down when this area was at a lower level in relation to the sea.

The chapter by Dr. Clark on early man and that on the Anglo-Saxon period by Mr. Lethbridge raise numerous points, which invite discussion. Not the least interesting of these is the question of the continuity of the population in the successive phases of the Bronze Age, the thickly populated Romano-British period, and Saxon times. If these and other matters have to be passed over, it is for lack of space, rather than of inclination. Cambridgeshire, so far, has indeed been fortunate in its county historians.

Comparative Study of the Lower Plants

Vergleichende Morphologie der niederen Pflanzen:

eine Einführung in deren Formbildung und Formwechsel auf entwicklungsgeschichtlicher Grundlage. Von Prof. Dr. Bruno Schussanig. Teil I: Formbildung. Pp. viii + 382. (Berlin: Gebrüder Borntraeger, 1938.) 36 gold marks.

THE appreciable advances in our knowledge of lower plants during the present century has led to the publication, especially on the Continent, of a large number of relevant works, but most of these deal with Algae or Fungi only as the case may be. A comparative treatment of the lower plants is therefore to be welcomed, and there can be no doubt that Prof. Schussanig has produced a book that will take its place among the accredited works on Thallophyta. This first volume is divided into four sections, two dealing with the cell and cell-division and two with the organization of the multicellular thallus. Here also is included a consideration of structure in relation to physiological function which is as unconvincing as most earlier accounts dealing with this topic.

It is natural that in a book of this scope new points of view should be advanced. Schussanig propounds the hypothesis that all parenchymatous types of thalli (for example, the polystichous Ectocarpales of Oltmanns) represent condensed systems of branching filaments, either uni- or multi-axial. This interpretation is extended not only to the parenchymatous Ectocarpales and Bangiales, but also to the Laminariales, Fucales, and even Dictyotales. Such a view has long been accepted for the Florideae, but the facts provided by the author in support of its application to the parenchymatous Phaeophyceae carry little conviction. It is not feasible to discuss this theory here, the more since additional evidence is to be furnished in the second volume. Schussanig also

reaffirms (p. 180) his view that the Conjugales are derived from a polyenergid ancestry, and a similar origin is suggested for the Red Algae, but it cannot be said that any strong evidence is adduced.

With the very wide range of topics discussed, it is perhaps inevitable that the treatment should in places be somewhat one-sided; for example, the problematic cytology of the Blue-Green Algae would seem to have merited a fuller discussion than is afforded it on p. 33, where really only Baumgärtel's point of view is considered.

The treatment of the Fungi is not as full as that of the Algae, a fact which is particularly noticeable in the very brief consideration of the plectenchyma of the former and in the discussion of parasitism. There are diverse minor points that call for criticism. As examples, we may note the reference to the spore as a normal stage in mitosis (p. 18) without mention of the fact that many recent authorities regard it as typical only of meiosis, the homology of the pseudocilia of Tetrasporaceae with flagella (p. 59) for which there appears to be no adequate evidence, the use of the term oonobium as synonymous with colony (p. 190), and the statement that growth-rings occur in the medulla of Laminariales (p. 375). The reference to Juller, rather than to Klebs or Pascher on p. 216 is misleading.

Despite such criticisms, however, Schussanig's book is often suggestive and stimulating, and the comparative treatment of many topics, especially in the first two sections, of great value. The book is essentially one for a specialist, since the matter is treated in such a way as to render it accessible only to those with considerable previous knowledge. It would, moreover, have fulfilled a more useful purpose had the text not been encumbered by the introduction of many new terms. The illustration is ample and excellent.

F. E. FRITSCH.

Farm and Garden Seeds

By Prof. S. P. Mercer. With a Section on the Seeds Act, 1920, by A. W. Munro. (Agricultural and Horticultural Handbooks.) Pp. 205+14 plates. (London: Crosby Lockwood and Son, Ltd., 1938.) 10s. 6d. net.

PROF. MERCER has produced an interesting and readable book on farm and garden seeds. While it may not make an appeal to a very wide public, it should find a place in the libraries of those for whom the author, in his preface, states he has attempted to cater; namely, the agricultural student, those concerned in the business of seed testing, and such others as are interested in how things grow and the methods adopted to ensure that the seeds they buy are what they purport to be and may reasonably be expected to germinate.

The book consists of five chapters, together with one appendix giving physical data about crop seeds and a second giving notes on practical seed testing. The first four chapters are by Prof. Mercer. After a short and somewhat condensed chapter on the formation, structure and growth of a seed, he goes on to give an interesting account of commercial seed production in Great Britain and indicates the sources of supply for other commercial seeds which are drawn from other countries. The chapter on seed testing bears the authoritative imprint of one who has for a number of years been in charge of an official seed-testing station. Prof. Mercer's final chapter contains a short description of each of the main crop and weeds seeds with the most beautiful and delicate illustrations of the seeds which the reviewer has ever seen. These illustrations are the author's own drawings and he is to be congratulated on them.

The final chapter in this book is contributed by Mr. Munro, of the Ministry of Agriculture, who, from intimate personal knowledge, gives an account of the provisions and administration of the Seeds Act of 1920.

An index, sufficiently comprehensive to make reference easy and quick, is included. R. R.

Biology for Pharmaceutical Students and Others

By Prof. S. Mangham and A. R. Hockley. Pp. viii+613. (London: Baillière, Tindall and Cox, 1938.) 21s.

LIKE many other introductory biology books recently published, this is a comprehensive, though elementary, survey of the subject; but it is difficult to believe that the authors were sufficiently alive to the needs of those for whom the book was specifically written, namely, students preparing for the preliminary scientific examination of the Pharmaceutical Society of Great Britain. The price, and also the length, are too great for a student's book, particularly in view of the fact that it is supposed to be of a preliminary nature; no doubt the latter determined the former. One explanation of the undue length is that the authors have borne in mind the students' later needs in pharmacognosy and physiology; but to forestall this later teaching in the student's first year is doubtful policy. In fact, it does not seem feasible to expect preliminary students

to assimilate profitably all that this book offers at the beginning of their professional studies.

Furthermore, especially in those parts dealing with plant physiology, there are too many names—usually surnames only—of research workers. These, too, in places seem to crop up indiscriminately. For example, in the two pages dealing with vitamins, apart from that of Hopkins, the names of Howard and Hirst only are mentioned. The account would be better balanced if these had been omitted. Again, in the section on the mechanism of photosynthesis, the first paragraph alone contains six names of workers from Priestley to Bousisingault. These can mean little to a visitor to the subject. They will make little impression on his mind and can only be a useless burden to the student, for whom the volume is written.

The book contains numerous excellent illustrations.

The Flight of Birds

By C. Horton-Smith. Pp. 182+17 plates. (London: H. F. and G. Witherby, Ltd., 1938.) 7s. 6d. net.

THIS book is a short popular account of bird flight. Some of its readers will be primarily interested in birds, others in aeronautics; it is perhaps inevitable that a few should be disappointed. The author is at his best when describing those attributes of the bird's wing which he has obviously studied at first-hand; he is not quite so convincing when translating the behaviour of the wing into aeronautical language. It is impossible at present to make any useful comparison between the air flow past a bird's wing during active flapping flight and that past a simple aerofoil, and it is therefore much to be regretted that Dr. Horton Smith does not always make it quite clear whether his statements apply to the wing of a bird or the 'wing' of an aeroplane.

Some of Dr. Horton-Smith's views may possibly be open to criticism on aerodynamical grounds, but as a biologist he has performed an extremely useful task in bringing into this small volume a large number of important observations which can scarcely fail to stimulate an interest in the subject.

Mineralogie von Bolivien

Von Friedrich Ahlfeld und Jorge Muñoz Reyes. Pp. vii+89+1 plate. (Berlin: Gebrüder Borntraeger, 1938.) 10.50 gold marks.

SINCE David Forbes in 1865 wrote his account of his researches in the mining districts of South America, many other British mineralogists have taken an interest in the rich mineral localities of Bolivia and the many rare species found there. A German translation of the Spanish "Mineralogia Boliviana" by Ahlfeld and Muñoz Reyes will be very welcome. In this book descriptions are given of 171 mineral species with brief mention of the places and modes of occurrence. Some of the occurrences recorded are new. There is a good index of localities, and the book is illustrated by crystal drawings and a frontispiece.

Nature of the Cyclol Bond

By Dr. Irving Langmuir, For. Mem. R.S., and Dr. Dorothy Wrinch

I

THE confirmation by X-ray data^{1,2} of C₆, the 268-residue cage structure proposed for the insulin molecule³, makes it of interest to consider the nature of the cyclol bond, upon the postulation of which this structure and the cyclol theory of protein structure in general⁴ depend. The making and breaking of a cyclol bond between an NH group of a polypeptide chain and a CO group of the same or of another polypeptide chain requires only the migration of an H atom thus:

The making and breaking of a cyclol bond is therefore a prototropic tautomerism, inter- or intra-molecular, which indicates a special type of binding of the H atom. (A recent investigation has shown that a similar situation actually exists in crystalline diketopiperazine⁵). As a prototropic tautomerism, it is to be sharply contrasted with the making and breaking of a peptide link which, requiring the intervention of another molecule, say water, may be written:

In order to direct attention to the fundamental difference between a prototropic tautomerism on one hand and a hydrolysis (or alcoholysis, etc.) on the other, it is convenient to talk in future of cyclol *bonds* and peptide *links*.

In current usage, the term protein is applied to anything having the chemical composition of amino acid condensation products. One class stands out as of paramount importance for the understanding of living matter, namely the crystalline globular proteins such as trypsin, pepsin and so on. These substances are already well defined in a number of ways, and it is with proteins belonging to this category that the cyclol theory is concerned.

Among the properties by which the substances are already characterized are the following:

(1) They have definite molecular weights which are discretely arranged.

(2) They contain certain numbers of various particular amino acid residues and these numbers are frequently powers of 2 and 3.

(3) They are soluble in water or salt solutions, but their solubility is affected by changes in pH.

(4) They denature under very slight stimulus.

(5) They spontaneously form monolayers of extreme insolubility.

(6) They exhibit a high degree of specificity in biological reactions.

It has already been shown that the cyclol hypothesis explains (1), (2), (4). With regard to (3) and (5), we may point out that the extreme insolubility of the monolayer formed from a soluble protein^{6,7} indicates that the globular protein has a structure in which hydrophobic groups can be completely masked, so leading directly to the idea of a cage structure which presented itself in the cyclol theory as a deduction from the geometry of polypeptide chains. The

Fig. 1.

CYCOL-6 (IN CENTER) WITH ITS TRIAZINE RING DOTTED. THE OPENING OF THIS RING YIELDS EITHER THREE DIKETOPIPERAZINE MOLECULES (SHOWN ON LEFT) OR A CLOSED POLYPEPTIDE CHAIN OF SIX RESIDUES (SHOWN ON RIGHT).

lacunae in the fabric allow ionized (and other) *R* groups to modify their positions profoundly in response to changes in pH, and indeed to lie inside or outside the cage. The spontaneous formation of protein monolayers from globular proteins in solution indicates that weak bonds only are broken. This we interpret to mean that, in the formation of monolayers, some or all of the cyclol bonds are opened, few or none of the peptide links being broken, so that protein monolayers consist of polypeptide chains partially or wholly decyclized, for the most part without open ends, the hydrophobic groups forming a separate phase in the surface. This type of structure explains many of their striking characteristics: for example viscosity, elasticity, etc.^{8,9}

It may be emphasized that the breaking of cyclol bonds yields different degradation products according to the path of fragmentation. Thus cyclol-6 yields three diketopiperazine molecules or a single 6-residue chain (Fig. 1). In standard circumstances, a preferential path of fragmentation, probably largely determined by the *R*-groups,

II

is to be expected*, and it may be presumed that one and the same structure will under standard conditions break down in a unique way. Further, if preferential paths of breaking cyclol bonds be postulated, preferential paths of making cyclol bonds must also be postulated. Experiments have recently been reported purporting to disprove the cyclol hypothesis, in which glycyl leucine and leucyl glycine dipeptides were mixed and glycyl glycine and leucyl leucine dipeptides were not formed¹⁰. Even if triazine rings were formed (and of this no evidence was offered), there seems no reason to suppose that the structure will break down to yield anything except the original molecules. We are therefore unable to accept these experiments as evidence against the cyclol hypothesis.

Fig. 2.

- — CHR, DIRECTION OF SIDE CHAIN INITIALLY UPWARDS.

These suggestions of preferred paths of fragmentation apply equally to the globular proteins characterized, on the present view, by a specific set of amino acid residues, in a definite spatial interrelationship. They imply that for each protein there are one or more points at which the breaking of cyclol bonds normally starts. Thus an insulin molecule forming a monolayer would form a specific set of wholly (or partially) decyclized polypeptide chains. In this way, we can explain the highly characteristic films formed by different proteins, which permit an unknown protein to be recognized instantly as insulin or pepsin or papain and so on^{7,8}.

From the point of view of biology, cytology and immuno-chemistry, however, the most striking characteristic of the globular protein is its high degree of specificity. This, we suggest, indicates an organized structure with its own characteristic modes of vibration, which depend on the nature and arrangement of the various constituent amino acids. Since the breaking and making of cyclol bonds is a prototropic tautomerism, we anticipate that in appropriate circumstances there may be a kind of resonance in the molecule which accounts for the stability of the cyclol fabrics and the cyclol polyhedra. The cyclol fabric, a fragment of which is shown in Fig. 2, contains no double bonds and thus Frank¹¹ believed that "the cyclol molecule in itself offers no chance of constructing a resonant system". But each triazine hexagon has three parallel hydroxyls on the three carbon atoms, the next triazine hexagons in the fabric having their three hydroxyls on the other side of the fabric. With a symmetrical structure of this kind, it seems highly probable that the protons, instead of being attached to individual oxygen atoms, lie between the oxygen atoms serving as hydrogen bonds between them. There may thus be a marked resonance involving the three oxygens and the three hydrogens. Furthermore, resonance on a larger scale between neighbouring triazine groups may also be expected.

This suggestion of intramolecular hydrogen bonds in the cyclol fabric is in line with the intramolecular bonds already postulated in a wide variety of compounds, including ice, alum, natrolite and other zeolites, oxalic acid dihydrate and formic acid, in which oxygen atoms are shown, by crystal structure data, to lie abnormally close together¹². Such a close distance of approach is evidence of considerable mutual energy of oxygen atoms, which can only be due to the presence of hydrogen between them¹³. For certain compounds, for example, salicylaldehyde and *o*-nitrophenol, the presence of intramolecular hydrogen bonds has been confirmed spectroscopically by the non-appearance of the hydroxyl band¹⁴. In these cases the oxygen-oxygen distance is about 2.5 Å., considerably shorter than the distance of 2.7 Å., that represents double the radius of the ion O⁻ and very much shorter than that for neutral oxygen. In the case of the cyclol fabric, hydroxyls are carried by three carbons in a triazine ring, which lie at the distance apart of $\frac{3}{2}\sqrt{6}a$, which is equal to 2.45 Å. if a , a length intermediate between the C-C and C-N distances is taken (as has so far been done) as 1.5 Å.

One of the most extraordinary properties of proteins is their specificity in biological reactions.

The haemoglobin in each different type of animal seems to differ in spectrum and in details of its behaviour with oxygen. We are thus forced to conclude that, in proteins, certain features of the molecule can transmit some effect to other parts of the molecule, particularly to prosthetic groups. Such transmission of chemical influence, although observable to some extent in such compounds as sterols, seems to exist in a unique degree in the proteins: in long-chain compounds, on the other hand, there is practically no evidence of such transmissions to distances of more than a few atoms. It is well known that in aromatic chemistry the resonance, for example in the benzene molecule, causes substituents in different parts of the molecule to have an effect on one another very different from what would be expected if no resonance occurred. The high specificity of the proteins therefore in itself seems to demand resonance to a degree greater than that in other known chemical compounds. It would seem that the cyclol polyhedral structure with its sets of rings within rings and its multiple paths of linkage between atoms (cf. Fig. 2) should be capable of just such a type of resonance.

May we not perhaps regard each diazine ring in the cyclol fabric as the analogue of an electrical resonant circuit, the natural frequency of which is determined by the character of the side chains in this ring? Then n resonant circuits coupled together would be characterized by n frequencies, no one of which being exactly what it would be if the resonant units were separated from one another. An electrical network, the resonant circuits of which have the geometry of the cyclol polyhedra, would give very close coupling between the adjacent hexagonal units. Thus the structure as a whole should possess a wide range of frequencies. The situation is somewhat analogous to that in the Debye theory where a crystal has a large number of modes of vibration. So in the protein the cyclol structure may be characterized by a whole spectrum of frequencies definitely correlated with the symmetry of the structure as a whole. Thus if a single factor disturbs the symmetry, it might have a profound effect upon some of the characteristic frequencies. If we imagine that these frequencies are important in the interactions between proteins and in funnelling the energy to certain parts of the molecule, we have a possible reason for the important effects produced by apparently minor changes in the structure of the protein molecule.

III

It appears that a strong case can be made out for the cyclol theory, since its implications, derived

by simple geometrical arguments, fits the facts summarized above. The theory depends upon one postulate which thus becomes of special interest, particularly as its formulation has occasioned some uneasiness in chemical circles. The question then arises as to the possibility of proving directly the existence or non-existence of cyclol bonds.

The work on protein monolayers indicates that only weak forces are required to open cyclol bonds. We are of the opinion that many chemical techniques are sufficient to rip open the cyclol fabric into polypeptide chains, so that the chemist by his very operations may destroy the structure he seeks to study. On this view, any apparent contradiction between the cyclol hypothesis (which regards the globular proteins as polypeptide fabrics) and the chemical data relating to proteins (which appear to show them to be polypeptide chains) disappears. The situation is thus reminiscent of that in quantum physics, where the conditions required for the observation of the position and velocity of an electron themselves modify the phenomena under study. Similarly, it has recently been suggested¹⁴ that enzyme studies do not permit the deduction that cyclol bonds do or do not exist in globular proteins. Direct knowledge of protein structure must therefore depend upon physical methods of investigation such as X-rays and spectroscopy, etc.

The picture of a globular protein with hydrophilic groups on its outer surface and hydrocarbon groups in contact within the cage is strikingly akin to the picture of the structure of certain micelles to which recent studies have led¹⁵. Ions, such as octyl trimethylammonium sulphate, which contain long hydrocarbon chains form micelles in very low concentration. It is found that the size of such particles corresponds to a sphere of radius about equal to the length of the individual molecules and it is shown that the micelles are spherical particles, in which the tails are crowded together in the interior and the hydrophilic heads form the outer surface. The micelles in soap solutions have a similar structure.

Little or nothing is known at present as to the path or the nature of protein synthesis. We see no reason to suppose that a cyclol fabric forms spontaneously from polypeptide chains. If on occasion such cross linking occurs, this is probably a relatively unstable state. The non-formation of cyclol bonds between simple molecules^{16,17} is thus irrelevant to the cyclol hypothesis and to the problem of the formation of complete globular protein molecules. Using the information obtained in recent studies of protein monolayers formed spontaneously, we deduce that, in the globular state, the CH_2 groups are completely masked from

the aqueous medium. The globular protein in water is thus pictured as having its outer surface predominantly hydrophilic, the hydrophobic groups lying close together in the interior of the cage. A protein molecule of the size of insulin must contain several hundred CH_2 groups to account for the insolubility of the monolayer which it forms. When two CH_2 groups come into contact, energy of the order of 2,000 calories per gram molecule is involved¹², totalling for a protein molecule of the size of insulin, containing at least 300 CH_2 groups, an energy of upwards of 600,000 calories. This suggests one possible factor in the formation of a protein cage molecule.

We would also direct attention to the difference between the stability to be expected when a single cyclol bond forms within or between polypeptide chains and when three cyclol bonds form a triazine ring, and to the still more striking difference to be expected between the stability of a piece of cyclol fabric and of a complete cyclol polyhedron. Undoubtedly there are a number of factors favour-

ing the complete polyhedral structure over and above any uncompleted cyclol structure. These may account for the existence of cyclol cages even if there should be an intrinsic instability in isolated cyclol bonds.

Remoras or Sucking-Fishes*

By J. R. Norman, British Museum (Natural History)

THE principal characteristic of the Remoras (*Echeneidae*), which with the Eocene *Opisthomyzonidae* form the order *Discocephali*, is the oval, laminated, adhesive disk, placed anteriorly on the broad, flat upper surface of the head, and representing the much modified spinous dorsal fin.

Fig. 1.

REMORA ALBIGESCENS (TEMMINCK AND SCHLEGEL). $\times \frac{1}{2}$.

In the form and position of the remaining fins, as well as in their general osteology,* these fishes resemble the *Percoids*, and especially the families *Pomatomidae*, *Carangidae*, *Rhachicentridae*, etc., and Regan¹ has suggested that they may well have

arisen from *Percoids* of this type. There are about ten existing species, grouped by some into five, by others into only two genera. In any event, they fall into two fairly well-marked groups: the *Echeneis* group, with a long, slender body, usually striped on the sides; and the *Remora* group, with a short, rather robust body, and a uniform brown, grey or black coloration (Fig. 1). Remoras occur in all warm seas, and one species is an occasional visitor to the British coasts. The larger species attain to a length of nearly four feet, but the smaller may not exceed fifteen inches.

In spite of its highly specialized structure, a close study of the cephalic disk reveals all the elements of a spinous dorsal fin². Each of the fin-spines is shortened, depressed posteriorly, and expanded transversely, and forms a pair of broad, flat laminae, the hinder parts of which are denticulated on their upper surfaces. Posterior projections of each pair of laminae are connected by ligament medianly, and there is a low fin-membrane joining them to the next pair. Viewed from below, it

* Substance of an address delivered before the Linnean Society of London on November 24.

may be seen that the large overlapping laminae actually represent the small lateral expansions of the radials generally to be found in the Percoids, and that the basals, although directed very obliquely posteriorly, have an almost normal form. The laminae composing the disk vary in number in the different species from nine to thirty-six.

It is a little difficult to visualize the manner in which this remarkable modification of the fin has been brought about, but Regan has suggested that the Remoras were probably derived from fishes which had, as the pilot-fish (*Naucrates*) has to-day, the habit of associating with sharks. "The spinous dorsal fin of the pilot-fish, and of other oceanic fishes of the same type, with the spines folded back within a groove, might possibly have some power of adhesion if the edges of the groove were applied to another object and the spines were then slightly raised."

As to the mechanism of adhesion it seems probable that when the flat surface of the disk is applied to the skin of the host, the marginal membrane creates a partial vacuum and a degree of adhesion is acquired. Then, by a slight raising of the transverse laminae, a further series of subsidiary vacuum chambers are created and the hold is firmly established. The denticulations on the laminae are evidently of use in preventing the disk from sliding on the surface of attachment and the fish avoids the danger of being swept away as its host makes its way through the water.

The power of adhesion is remarkable, and when firmly attached a Remora can be dislodged only with difficulty. A backward pull only tends to raise the edges of the laminae and thus to increase the hold, but by sliding the fish forward, the laminae are lowered and it can be detached more or less readily. Experiments made with living fishes have shown that a full-grown Remora can withstand a vertical pull of more than 40 lb. without giving way. Sewell³ has made some interesting observations on living Remoras, and has shown that, while holding on, all movements of the fish, except those associated with respiration (that is, of the mouth and gills) seem to be suspended. "In the case of a fish that had been well hooked, it was found that by allowing the fish to attach itself to a glass plate it would hang motionless, while the hook and a great part of the fish's jaw was out out!" It appears that the action of the sucker causes inhibition of all movement of the body and tail, and in this connexion a detailed study of the nervous mechanism involved would be of interest.

The Remoras are carnivorous in habit, and, judging from the stomach contents of captured specimens, feed mainly upon other fishes, which they catch freely in the water. They must also obtain a share of the host's meals at times. The advantage of the association to the Remora would seem to be twofold: it obtains transport, without effort on its own part, to fresh feeding-grounds, and it gains a measure of protection from the proximity of its formidable partner. The larger species attach themselves to the surface of the body of the host, generally in the region of the belly or sides, but some of the smaller species are not infrequently found inside the mouths of whales, sharks, giant rays, etc., and others regularly shelter within the branchial cavities of swordfishes, sailfishes, barracoutas and other large teleosts. It has been suggested that the frantic leaps of sail-

Fig. 2.

OPISTHOMYZON GLARONENSIS (WETTSTEIN). FROM WETTSTEIN. $\times$ ABOUT $\frac{1}{2}$.

fishes are made in an endeavour to get rid of the unwelcome guests in the gills. There is some evidence that certain species of Remoras are ordinarily associated with certain definite hosts, but further data are necessary on this head⁴.

A fossil Remora—*Opisthomyzon glaronensis* (Wettstein)⁵—from the Upper Eocene of Switzerland, is of considerable interest (Fig. 2). Here the adhesive disk consists of about six segments only, and, in addition to being smaller and narrower than its modern counterpart, is placed farther back and does not reach the interorbital region of the head. Further, the broader opercles and widely forked caudal fin suggest that the Eocene form was a stronger and more active swimmer than its descendants. "Perhaps," as Regan remarks, "it swam more and held on less than they do." The only other fossil Remora so far described is *Echeneis carpathica*, Szajnoch, from the Oligocene of Poland, but this is a comparatively modern form.

As might be expected, the available embryological evidence, although still far from complete, is also of considerable interest. Until recently, nothing at all was known of the early stages in the life-history of these fishes, but in 1926 Tani⁶ published preliminary descriptions and figures of

post-larval stages of both *Echeneis lineata* and *Remora remora*, based upon material obtained in the Atlantic by the *Dana* and other Danish vessels under the direction of the late Dr. Johannes Schmidt. His figures show that the disk is developed ontogenetically in the position normally occupied by the spinous dorsal fin, and that it later undergoes a gradual migration anteriorly. Thus, in specimens of *Remora remora* less than 8 mm. in length, no disk is visible. In an example of 9.8 mm. it has the appearance of a narrow oblong structure situated just behind the head: no laminae are yet visible macroscopically, but can be seen to be developing in prepared sections. In a specimen of 12 mm. the anterior edge of the disk lies just behind the eyes, in one of 18 mm. it is level with their anterior edges, and in one of 25 mm. it is well in front of the eyes. Sanzo⁷ has described and figured the pelagic eggs and early larval stages of *Remora remora* from the Mediterranean, but his account adds little to that of Tåning, whose detailed paper will be awaited with interest. Tåning⁸ has shown that the pelagic free-swimming post-larval life is of somewhat short duration, since *Remora remora* joins its host at a length of 30–40 mm., while at a length of 50 mm. the adhesive disk of *Echeneis lineata* has attained its full efficiency.

In the later stages of development, it may be noted that in the species of the *Echeneis* group the young have a peculiar type of caudal fin, the middle rays being prolonged to form a narrow pointed process. This gets progressively shorter with age, the hinder margin of the fin becoming plumose and finally more or less concave⁴.

There is a notable and persistent myth or legend associated with the Remoras, concerning the alleged powers of these fishes to retard the progress or even to stay the course of a ship⁹. This idea is inherent in the names given to the fish by the Greeks and Romans—*Echeneis* (one that holds back a ship) and *Remora* (a holding back). The earliest reference to the fish itself is that of Aristotle, but there seems to be reason for supposing that he never saw the fish in the flesh. The fact that he refers to it as a fish "which some call the *Echeneis* or 'ship-holder'" suggests that the belief was already current in the fourth century B.C. The credit for the first definite reference to the ship-retarding powers of the Remora belongs to Ovid, but the most detailed account is that of Pliny. The latter asserts that the naval battle of Actium was lost by Mark Antony because at the critical moment the praetorian ship was delayed by a fish of this kind. He also tells us that the death of the Emperor Caligula was presaged by a Remora arresting the progress of his galley on the voyage to Antium.

In addition to stopping a ship, states Pliny, a Remora could stay or hasten an *accouchement* or a law-suit! Later writers repeated this legend, with or without embroideries, and it remained popular throughout classical, medieval and renaissance times. It is of some interest to note that the term Remora has attained a definite place in literature, especially in English literature of the sixteenth and seventeenth centuries. Rabelais, in order to illustrate the law's delays, refers to "your beneficial remoras, that is the eternity of law-suits: the needless let that keeps them undecided". Spenser, in his "Visions of the World's Vanitie", has the following:

"All suddenly there clave unto her keel
A little fish that men call Remora,
Which stopt her course, and held her by the heel,
That wind nor tide could move her thence away."

Also Ben Jonson applies the term to describe a tedious bore (Poetaster), thus:

"Death, I am seized on here
By a land remora."

Various attempts have been made to illustrate the legend, and one of the more curious is shown

Capitulum. xxxvj.

Fig. 3. ONE OF THE EARLIEST KNOWN FIGURES OF *Remora* OR 'SHIP-HOLDER'. FROM JOHANN VON CUBE'S "ORTUS SANITATIS" (2ND ED., LEIPZIG, 1490).

Fig. 3. ONE OF THE EARLIEST KNOWN FIGURES OF *Remora* OR 'SHIP-HOLDER'. FROM JOHANN VON CUBE'S "ORTUS SANITATIS" (2ND ED., LEIPZIG, 1490).

in Fig. 3. This is to be found in the "Ortus Sanitatis" of Johann von Cube, first published at the end of the fifteenth century, and shows some six or seven Remoras adherent to a ship.

Although it is possible that a number of attached Remoras might retard somewhat the progress of a small boat, it is inconceivable that one (or even a dozen) fish could exert sufficient power to affect the course of a vessel of any size.

As Gudger¹⁰ has pointed out, the more probable explanation of a ship being suddenly held up or losing way is a physical one—the phenomenon known to seamen as 'dead-water'.

In various parts of the world the natives make use of leashed Remoras to capture large fishes, dugongs, turtles, etc., and many accounts have been given by travellers and others of the methods employed¹¹. Often a ring is fastened round the

Remora's tail, and to this is attached a long cord. The fish is kept in a bucket of water until, say, a turtle is sighted near the surface, and it is then released so that it may attach itself to the quarry:

Figura hac desumpta est ex tabula quadam descriptionis orbis terrarum.

Fig. 4.

FISHING WITH THE REMORA. FROM CONRAD GESNER'S "HISTORIAE ANIMALIUM", LIB. 4, 1558.

Remora and turtle are then pulled in together. Some skill is required in playing the 'catch', for any undue strain on the line may detach the Remora or, what is more probable, pull the ring

from its tail. In the Torres Straits, according to Dr. A. C. Haddon, a hole is bored through the tail, and through this a line is passed and made fast. A second line is passed through the jaws and out through the gill-openings. When the canoe sets out the fish is towed through the water by the head-line, and if it should attach itself to the boat it can be released by a forward pull when required.

What appears to be the earliest account of the employment of the Remora in this way occurs in Peter Martyr's account of the second voyage of Christopher Columbus to the New World, published in the early part of the seventeenth century. The story has been repeated by many writers of this and later times, and appears in the early works on natural history of Gesner (Fig. 4), Aldrovandi and others.

Obituary Notice

Mr. Emile Mond

MR. EMILE MOND died at the age of seventy-three years on December 30, 1938. He was a nephew of the late Dr. Ludwig Mond.

Emile Mond received his early education in Paris at the Collège de Sainte Barbe and at the Lycée Condorcet and specialized in chemistry at the Polytechnicum, Zurich, where he took his diploma. He began his technical career in England with Brunner, Mond and Co. with whom, at first, he did not stay very long, leaving them to found the West Indies Chemical Works in Jamaica with his friend and former fellow-student, Dr. Emile Bucher of Geneva. Afterwards, he returned to Great Britain and became technical assistant to his uncle, specializing in patent work. Later, he joined the board of Brunner, Mond and Co., Ltd., and the Mond Nickel Co., Ltd., becoming vice-chairman of the latter. In addition, he held the chairmanships of the South Staffordshire Mond Gas Co., the Power-Gas Corporation, Ltd. and Ashmore, Benson, Pease and Co., Ltd.

Emile Mond married Angela, youngest child of the late James Henry Goetze, who has been so closely identified with his many benefactions and scientific and social activities. From its beginning, he was intensely interested in the Institut Français du Royaume Uni which was founded by Madame

Marie Bohn and, being greatly concerned at the lack of educational facilities in Great Britain for French and Belgian refugee children, he provided for the establishment of the Lycées de Londres in May, 1915. These institutions became so important that the British Government provided a house for them and the Lycées became part of the Institut Français. Later, in 1921, they were formally recognized by the French Government and affiliated to the Université de Lille. In recognition of this important work, Emile Mond was made Officier de la Légion d'Honneur by the French Government and Officier de l'Ordre de Léopold by the King of the Belgians. In 1919, Emile Mond established the 'Francis Mond' professorship of aeronautical engineering—the first chair in that subject in a British university—at Cambridge in memory of his son, who was killed while flying in France in May 1918.

Although he always under-estimated his own ability and attainments in the science, Emile Mond was keenly interested in the advancement of chemical knowledge and, when he could spare the time, delighted to visit laboratories where original investigations were proceeding and invariably was able to contribute usefully to the discussion of the results. It was this interest in the subject and his desire to help in the attainment of new knowledge which led

him to accept the honorary treasureship of the Faraday Society in 1930, succeeding his cousin, the late Sir Robert Mond, and in 1931 he also became honorary treasurer of the Chemical Society. The work of this latter office is particularly onerous, and Emile Mond never spared his efforts on behalf of the Chemical Society and of the Faraday Society. His work was carried out with meticulous care and foresight, and during the time he has looked after their affairs—he held both offices at the time of his death—the two Societies have made outstanding progress, and the publication and discussion of new knowledge in chemistry have been greatly extended.

Emile Mond was a man of rare discernment, great modesty and charm. Severely critical of his own efforts, he was always appreciative of those made by others. Only a few have any idea of his great generosity during many years, and this generosity was guided by his intense desire to help the younger generation, to advance science and other branches of knowledge and to extend international good will. For many years, Mr. and Mrs. Emile Mond have made their houses delightful centres of refinement and culture for their numerous friends in this and many other countries.

Emile Mond was a type of man unfortunately too rare in these days. His greatest happiness was in helping others towards a fuller appreciation of things that are worth while. He will be greatly missed, and

to Mrs. Mond and the family very many who were privileged to know this truly great man will wish to tender their deepest sympathy.

CHARLES S. GIBSON.

We regret to announce the following deaths:

Prof. G. Barger, F.R.S., regius professor of chemistry in the University of Glasgow, on January 5, aged sixty years.

Mr. J. O. Borley, O.B.E., formerly fisheries adviser to the Colonial Office, known for his work with the "Discovery" Committee in connexion with the international control of whaling, on December 30, aged sixty-six years.

Mr. Reynold Bray, ornithologist of the British Canadian Arctic Expedition, aged twenty-seven years.

Prof. H. A. Cummins, O.M.G., emeritus professor of botany in University College, Cork, on December 31, aged seventy-four years.

Sir Robert McDougall, known for his services to the National Trust and his interest in agricultural research at Rothamsted, on December 15, aged sixty-seven years.

Prof. M. Pavlova, professor of palaeontology in the University of Moscow, aged eighty-four years.

Prof. L. G. Schnirelman, professor of mathematics in the University of Moscow, aged thirty-one years.

News and Views

Sir Frank Smith, G.B.E., K.C.B., F.R.S.

SIR FRANK EDWARD SMITH will relinquish on January 31 his appointment as secretary to the Committee of the Privy Council for Scientific and Industrial Research, a post which he has held with distinction for the last ten years. Born in Birmingham in 1876, he gained a national scholarship in physics at the Royal College of Science in London. He was one of the first assistants appointed by the late Sir Richard Glazebrook when the National Physical Laboratory began in 1899, and he was superintendent of the Physical Department of the Laboratory from 1901 until 1920. During this time he did a great deal of advanced original research work, introducing many novel methods, but he was never satisfied with the results obtained until he had checked them by other methods. He designed and helped to construct many new instruments and devices, and his results on the measurement of absolute units showed an accuracy unrivalled at the time. Accounts of many of these researches, some of them written by himself, will be found in Glazebrook's "Dictionary of Applied Physics", vol. 2. The gradual evolution of the current balance, in which the electric attractions between currents in coils were balanced by weights, so that it became possible to measure a current in absolute measure and thus determine the ampere, was a triumph of

research. The agreement now arrived at by international physicists as to the absolute value of the units justifies the great skill and time expended in measuring them, in which Smith took a leading part. In addition to all the routine and research work he did, he was always pleased to discuss with his colleagues the problems in which they were mutually concerned. Among other important work he did at the Laboratory was his work on the 'current weigher' in collaboration with Ayrton and Mather. He co-operated with Duddell and Glazebrook in perfecting radio telegraphic apparatus for direction finding, and he also co-operated with some of the physicists at the Bureau of Standards, Washington, D.C., in perfecting standards of electromotive force. His work with Rosa of this laboratory on standards of inductance was also of great value.

FROM 1920 until 1929, Sir Frank was director of scientific research, Admiralty; from 1929 until the present time he has been secretary to the Department of Scientific and Industrial Research. He has been one of the secretaries to the British Association for Advancement of Science (1922-29) and a secretary of the Royal Society from 1929 until 1938. As an administrator he has been most successful, partly due to his tact and the many friendships he formed with leading men in the industrial and engineering

world. He forms an admirable link whereby the industrialist can get into touch with Government departments—and vice versa. During recent years, in furtherance of his duties, he has made voyages to South Africa, the Argentine, the United States, etc. He has been of great service to the Royal Society and has given lectures, generally in connexion with electrical subjects, to many scientific and industrial societies in towns in all parts of the kingdom. He has been president of the Physical Society and of the Junior Institution of Engineers, and has been given various degrees by universities in Great Britain and abroad. He has been awarded the Hughes Medal of the Royal Society, the Duddell Medal of the Physical Society and the Faraday Medal of the Institution of Electrical Engineers. All men of science will hope that his advice will be available to us for many years to come.

Prof. E. V. Appleton, F.R.S.

H.M. THE KING has approved the appointment of Prof. E. V. Appleton to succeed Sir Frank Smith as secretary to the Committee of the Privy Council for Scientific and Industrial Research. Prof. Appleton, who will take up his new appointment on February 1, has been Jacksonian professor of natural philosophy in the University of Cambridge since October 1936. He is a fellow of St. John's College, Cambridge; and, after a period of service on the staff of the Cavendish Laboratory, he held the post of Wheatstone professor of physics in the University of London during 1924-36. Prof. Appleton's research work has included a study of the operation of thermionic valves and their associated circuits, the nature and origin of atmospheric and the phenomena associated with thunderstorms; but he is perhaps best known for his investigations on the ionized regions of the upper atmosphere, and their influence on the propagation of radio waves. In this field the results of his work have been of far-reaching importance both in connexion with our knowledge of the physics of the atmosphere and also in assisting the general development of long-distance radio communication. It is well known that by using waves sufficiently short to penetrate the Heaviside layer, Prof. Appleton was able to demonstrate the existence of a second, similar but denser, ionized region at a greater altitude. Most of this research has been conducted on behalf of the Radio Research Board, of which Prof. Appleton has been a member for many years. The work itself has brought him international recognition: he was awarded the Morris-Liebmann prize of the American Institute of Radio Engineers, in 1929 and was elected a vice-president of the Institute in 1932. He has been president of the Union Radio Scientifique Internationale since 1934, and in this capacity he conducted the general assembly of the Union which took place in Italy last September.

Prof. P. G. H. Boswell, O.B.E., F.R.S.

PROF. P. G. H. BOSWELL, who has resigned from the professorship of geology at the Imperial College, is followed by Prof. H. H. Read, who succeeded him

as George Hardman professor at the University of Liverpool. After some early work on the glacial deposits of eastern England, Prof. Boswell's researches on the Tertiary rocks of the London Basin extended the study of detrital minerals originated by H. H. Thomas to the elucidation of problems of genesis, provenance and age. He thus gave a new life and meaning to the old "test by included fragments", inaugurated a method of research which has been widely followed, threw new light upon processes of sedimentation, and laid the foundation for his work on sands and other mineral substances of vital importance to the metallurgical, glass and brick-making industries during the War. He also devoted much attention to the Chalk, its movements and its sub-Tertiary surface, to the history of the Suffolk rivers, to the Pliocene 'Crag', and to the classification of the Glacial Drifts especially in their relation to early man, on which he gave his presidential address to Section C of the British Association at York. As an authority on East Anglia, his services were called upon by the Geological Survey for three of its memoirs, while he contributed a series of articles to the 'Encyclopædia Britannica' and to 'Regionale Geologie' and its successor the 'Handbook of the Geology of Great Britain'.

WHEN Prof. Boswell moved to Liverpool to take the chair of geology there, he tackled the difficult area of the Denbighshire Moors, which had been long neglected by geologists, and started a series of papers on their geology which he has since continued. He was able to give advice on the geological conditions of the Mersey valley which contributed no little to the success of the new tunnel; and, later, he was sent out to adjudicate on disputed evidences on the age of human skeletons obtained from Kanam and Kanjera in Kenya. In spite of all this research and the stringent duties of his chair, he found time to make a translation of Heritsch's 'Nappe Theory on the Alps', which an eminent German professor was heard to say he preferred reading to the original. He has acted as president of the Prehistoric Society, as secretary of the Geological Society, and as a general secretary and treasurer of the British Association. In his latter positions he has taken an active part in the recent increased activities of that body. We may look forward with confidence to a rich harvest of further research from him now that he is free from the heavy strain of professional duties.

Technical Non-Teaching Staff in Laboratories

AN important unit on the science side of educational establishments is that which includes the minor technical staff, namely, laboratory and technical assistants, workshop assistants, store keepers, etc., and science teachers know from experience the help which a really good laboratory assistant renders to a department. This is particularly the case in those departments which employ only one assistant. His experience, probably gained from the problems encountered while performing the tasks associated with his post, covers a wide range, depending upon the particular type of science department in which

he is engaged. One agrees that the services rendered by these assistants should be adequately recognized from a financial point of view. In addition, their conditions of service should be such that they are encouraged to take a real interest in their work, and are given facilities for proper training. There is no need to stress examples of such assistants attaining the highest academic distinctions; but it is a fact that many of them, given help and encouragement, display marked resources, particularly in experimental technique. The conditions of employment are not too good in some institutions, and so within the past three or four years a Technical Non-Teaching Staff Branch of the National Union of Public Employees has been formed to safeguard the interests of such technical assistants.

THE objects of this branch, which is of national character, although its activities have been confined mainly to London, include the following: to improve the status of all stewards and assistants employed in the laboratories, or workshops, of any educational establishment, and to secure a fair wage, reasonable hours of work, suitable working conditions, together with a reasonable expectation of permanent employment. One obvious difficulty is the grading of assistants in university laboratories with those employed in secondary schools. There is no comparison between the ability, responsibilities and skill of the members in the two classes. It must also be remembered that salaries and conditions of employment in educational institutions are bound to vary with the locality. The Branch of the Union is also endeavouring to organize suitable training courses for juniors, and specialized practical classes for others. It is proposed that these classes shall extend over a minimum period of five years, the final specialization being in biology, chemistry or physics—for some reason no mention is made of engineering. After successfully passing through the course, the candidate would be entitled to receive a nationally recognized certificate, or diploma, which would be a guarantee of competence in laboratory management. It must be remembered, however, that the Institute of Physics has a scheme in operation, whereby certificates are awarded to technical assistants in physics who attend approved courses of instruction, and pass examinations in accordance with certain regulations. Other activities of the Branch of the Union include educational visits to laboratories, factories, etc., and it is hoped to arrange for demonstrations of new apparatus, experiments, etc., similar to those held in connexion with other associations. The secretary of the Branch is Mr. E. J. Chilton, 361 Kingston Road, Ewell, Surrey.

Data on the Ionosphere (F_2 Region)

It is important to the radio engineer to know the highest frequency radio waves returned from the ionosphere at any time or season, since this critical frequency represents the division between those frequencies which can be used for long-distance radio communication and those which are suitable for transmission only over quasi-optical ranges. The

same knowledge is of importance also to the geophysicist, since it provides him with a reasonably accurate statement of the most intense ionization existing at any level in the ionosphere. For some years past, the Radio Department of the National Physical Laboratory has conducted a comprehensive investigation into the propagation of waves as part of the programme of the Radio Research Board of the Department of Scientific and Industrial Research. Included in this work are daily measurements of the height and critical frequencies of the various regions of the ionosphere made at the field station of the Radio Department at Slough (lat. $51^\circ 29' 30''$ N., long. $0^\circ 33' 30''$ W.). When electric waves from a radio transmitter pass through the ionosphere, they are split into two components with different velocities and opposite senses of circular polarization, under the influence of the earth's magnetic field. The region capable of returning the higher radio frequencies to earth is known as the F_2 region and the highest frequency which can just be returned by that region is known as the critical frequency and refers to the extraordinary component of the wave. It is, however, more convenient to measure the ordinary component, and in the northern hemisphere the plane of polarization of this component has a left-handed direction of rotation when looking along the direction of propagation. The critical frequency for this component is generally about 0.7 Mc./s. lower than that of the extraordinary component in the case of the results quoted. The daily measurements are carried out with waves returned from the ionosphere at vertical incidence, and the values of height and critical frequency of the regions studied refer to this condition. The corresponding values for oblique incidence can be derived from these results, and from these, the conditions for long-distance communication can be deduced.

In view of the widespread use of long distance radio communication and broadcasting on the short wave band between 10 and 100 metres (3 and 30 Mc./s.), it is proposed that the ionospheric data relevant to this band should be made available as a special service to those interested in the subject. Typescript copies of monthly tables, including sufficient data for any day to enable a simple curve to be plotted showing the relation between height and critical frequency of the region under consideration, and beginning with January 1939, is now available at 2s. 6d. per annum for subscribers in Great Britain or in the Empire overseas, and 5s. per annum for foreign subscribers. Applications, with the appropriate remittance, should be addressed to the Director, National Physical Laboratory, Teddington, Middlesex. Arrangements have also been made by which those desiring to obtain early information on the state of the ionosphere as soon as the data are available may obtain them by telephoning the Radio Research Station (Slough 1560) between the hours of 10 a.m. and 4.30 p.m. Those wishing to avail themselves of this service should write to the Director of the National Physical Laboratory asking

Science and Faith

THE meeting of the American Association for the Advancement of Science, which took place at Richmond, Va. during December 27-31 will be memorable in the annals of science as being the first to mark that closer co-operation between this body and the parent British Association, to which Lord Rayleigh, in his presidential address to the latter body at Cambridge in August last, looked for aid in promoting international amity. No less will it be remembered as the occasion of the delivery of the two addresses of which the main parts are given in the following pages.

In these pronouncements, two of the leaders of scientific thought in the United States and Great Britain at the present day, Prof. G. D. Birkhoff, the president of the American Association, and Sir Richard Gregory, chairman of the newly formed Division for the Social and International Relations of Science of the British Association, declared their faith in the mission of science in the resolution of the maladjustments which lie deep-seated at the root of the difficulties and the dangers with which the world of to-day is faced. In the words of Prof. Birkhoff, "The increasing number of unco-ordinated theories and mechanical inventions confuse and chill many of us. Man is felt to be a tragic detail in a vast incomprehensible whole, and the old sense of values seems to become less and less real". But he went on to show in his lucid analysis of the function of intuition, reason and faith in the approach to his hierarchy of five ascending levels in the nature-mind spectrum, that while reality is to be attributed to each and all, at each level there is an ever-widening succession of abstract ideas, each explaining imperfectly some aspect of the stupendous whole; but that at the

social level a fundamental truth of transcendent importance is truth and good will in all social relationships. In concluding that a new injunction has been laid upon the spirit of man to know and to understand ever more broadly and deeply, he added that in the daring effort of the man of science to extend knowledge there arises a spontaneous faith which is the most powerful incentive and the best guide to further progress.

In essence, Sir Richard Gregory's address is complementary to that of Prof. Birkhoff. Just as Prof. Birkhoff holds that faith in the ultimate truth of certain fundamental principles is the guiding star of the man of science, so Sir Richard shows that in the study of man and society from the earliest ages it is seen that faith in an unseen power which lies behind the appearance of things is a fundamental component of man's nature. He goes on to demonstrate that, in the course of the development of mankind, faith also has developed, not only in the conception of the object of devotion and the relation of that object to the universe, but also in the extension of the circle of those to whom the ethical system which is its accompaniment is made to apply. Although it has to be admitted that the development of spiritual and ethical concepts has been retarded in comparison with material development, nevertheless it is in the recognition of this conception of a process of continuous development in theological and ethical ideas that Sir Richard sees hope for the ultimate approach one to the other of religion and science, while in the fundamental urge of faith he sees a guide pointing the way to an enlargement of the ethical ideal, in which present differences and antagonisms may be resolved.

Intuition, Reason and Faith in Science*

By Prof. George D. Birkhoff, Harvard University

FROM the earliest times scientific ideas, even when crudely conceived, have been of immeasurable importance, not only for man's material advancement and control over Nature, but also in modifying and expanding his philosophic and religious outlook. In the effort to obtain a better understanding of his place in the cosmos, he is compelled to proceed largely by considerations of analogy based upon supposed or actual fact. So he turns more and more toward the ever-widening vistas suggested by science in its continual discoveries of new truth.

To-day, the significance of science as a principal source of revelation is almost universally recognized. Thus recently, on behalf of Pope Pius XI, Cardinal Pacelli spoke before the Pontifical Academy of Sciences concerning the enlightenment that comes from "the potent streams of the natural and rational sciences and the great river of revealed wisdom". He said that the former are found "wherever man looks for and finds truth". As for "the great river of revealed wisdom", is it not to be found in all the absolutely sincere utterances of poets, philosophers and prophets, based on the relevant knowledge of their day and made after deepest meditation? It would seem that such utterances are in essence similar to the pronouncements of the scientist. Is not the vague, prophetic conjecture of Pythagoras that Nature is mathematical as true as Newton's more precise law of gravitation? From this point of view, the great streams of revelation seem to merge insensibly into one.

Nevertheless, the immediate effect of scientific advances is often very disquieting. The strong opposition long shown to the Darwinian theory of evolution bears witness to this fact. Similarly at the present day, the ever-increasing number of unco-ordinated theories and mechanical inventions confuses and chills many of us. Man is felt to be a mere tragic detail in a vast incomprehensible whole, and our old sense of values seems to become less and less real.

To persist in such an attitude of discouragement

is unjustified. Every individual has implanted within him the desire to understand his role in the existing order. He feels an inalienable right to find out his duties and privileges as a citizen of the universe. By the light of any new knowledge he is always certain to gain deeper insight into his position. The wise advice of our own great Emerson comes to mind: "Fear not the new generalization. Does the fact look crass and material, threatening to degrade thy theory of spirit? Resist it not: it goes to refine and raise thy theory of matter just as much."

What, then, are some of the larger points of view which are suggested by science to-day? In attempting a reply, I can of course only offer a personal interpretation, inevitably reflecting the fact that I speak as a mathematician having some acquaintance with physics.

Let us observe in the first place that our universe presents antipodal aspects—the objective and the subjective, the impersonal and the personal. If we take the objective aspect as more fundamental, we put our emphasis on the notion of reality; and if we start from the subjective, we prefer to speak of knowledge. In either case we are able to discern a kind of nature-mind spectrum; for there appears a roughly given hierarchy of five ascending levels—mathematical, physical, biological, psychological and social. Each level has its appropriate special language. The basic corresponding concepts are respectively: *number* at the mathematical level; *matter* at the physical level; *organism* at the biological level; *mind* at the psychological level; and *society* at the social level. If we choose to select one of these as somehow more real than the others, a great distortion arises in our point of view. For example, if we regard the physical level as the most fundamental, we become materialists. But why make such an unnecessary choice? The languages of the various levels are essentially independent of one another, and the observed laws are best expressed in their own natural terms. Why mix up the levels of knowledge unnaturally? Does it clarify our ideas of social justice to try to explain it in terms of the reactions between protons and electrons in the brain?

* From the address of the president of the American Association for the Advancement of Science delivered at Richmond, Va., on December 27, 1938.

These considerations bring us to a first general point of view towards the levels of knowledge: it is desirable to accord reality in equal measure to all kinds of knowledge everywhere, and so to view the universe as broadly and impartially as possible.

Another very important observation is that in order to understand the various facts and their interrelations we must always use abstractions, that is, conceptual tools of a logical or mathematical nature. Contrary to opinions which prevailed until recently, any abstraction serves only limited specific ends. At best it will enable us to grasp more clearly some small fragment of reality. For example, by use of the abstraction of Euclidean geometry, and in that way alone, we understand the nature of space with a considerable degree of exactitude; and yet to-day scarcely any physicist would ascribe objective reality to space in itself. It has been Einstein more than anyone else who has taught the scientific world the true role of Euclidean geometry by means of his theories of space-time and relativity. More generally, we have come to realize that our only approach to a better understanding of the world is by means of a widening succession of abstract ideas, each explaining imperfectly some aspect of the stupendous whole. This is a second synthesis deserving of especial emphasis.

Thirdly, I would state a fundamental truth about the social level, which in some sense is the highest level of all: the transcendent importance of love and good will in all human relationships is shown by their mighty beneficent effect upon the individual and upon society.

Thus I have begun by presenting very briefly three important articles of my personal faith. It is my especial purpose to show how this phenomenon of faith arises inevitably in the mind of the scientist whenever he tries to evaluate technical conclusions in his special field. In doing so I shall discuss the role of intuition, reason and faith in science, first at the mathematical and physical levels, and then more briefly at the biological, psychological and social levels. This will lead me in conclusion to formulate two other items of my personal *credo* in the hope that they may be worthy of attention.

By way of definition it must be indicated first what is meant by intuition. There are certain elementary notions and concepts which come spontaneously to the minds of all who observe, experiment with and reflect on a specified range

of phenomena. Such generally accepted ideas or intuitions constitute the consensus of reaction of intelligent men to a certain part of the world of fact. John Stuart Mill has said, "The truths known by intuition are the original premises from which all others are inferred." It is in this sense that I shall refer to intuition. By reason I shall mean the rational superstructures which may be erected upon the basic intuitive ideas by means of deductive or inductive reasoning. These superstructures will also be accepted by all who are able to follow the sequence of logical steps involved. By faith I shall mean those heuristically valuable, more general points of view, which are beyond reason, and sometimes in apparent contradiction with one another, but which to the individual concerned seem of supreme importance as he endeavours to give his conclusions the widest possible scope.

It is clear that in this way we obtain a basic classification of knowledge into three easily distinguishable types. Let us consider the occurrence of these types at the various levels of knowledge.

INTUITION IN MATHEMATICS

By continual crude experimentation with classes of concrete objects, man has come gradually and inevitably into the possession of certain numerical ideas. In particular he has been led to think of the positive integral numbers 1, 2, 3 . . . as entities which exist in almost the same sense as the objects themselves. This concept finds its realization in the designation of the integers by corresponding marks 1, 2, 3 . . . Such integers are found to be subject to certain simple arithmetic laws, and these laws are regarded as intuitively true.

The integers form the basis of a great part of mathematics. For it is found that with their aid one may construct fractions and, more generally, real and imaginary numbers. In the course of the centuries, mathematicians have thus built by processes of pure reason the elaborate structures of algebra, the theory of numbers and analysis. An extensive array of beautiful and useful theorems has been deduced.

Similarly in geometry—which in its origin may be regarded as the most elementary branch of physics—we experiment with rigid material objects and arrive readily at the notions of idealized small rigid bodies or 'points' and of idealized 'lines' and

'planes'. Then we observe that certain postulates hold, such as the familiar ones of Euclid. By means of these postulates which embody our intuitions, we are able by deductive reasoning to arrive at other geometrical theorems, including such results as the celebrated Pythagorean theorem which shows us in particular that a right triangle with legs of 3 units and 4 units in length has a hypotenuse of exactly 5 units in length. The vast mathematical domain called 'geometry' has arisen from these elementary geometrical facts as a primary source.

There are many other abstract mathematical structures besides those just alluded to. In all cases it is found that they are made up of certain accepted intuitions (or postulates) and their logical consequences.

Now what I desire particularly to point out is that the mathematician goes far beyond such generally accepted clean-cut assumption and conclusions, in that he holds certain tacit beliefs and attitudes which scarcely ever find their way into the printed page. Yet these form none the less part of a considerable oral tradition. For example, he believes in the existence of various infinite classes, such as that made up of all the integers. He believes also that the whole body of strict logical thought called mathematics is self-consistent: in particular, when he finds that the number π admits of diverse forms of expression, as, for example,

$$\pi = 4 \left[\frac{1}{1} - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \dots \right]$$

and

$$\pi = 2\sqrt{3} \left(\frac{1}{1} - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \dots \right),$$

he feels absolutely certain that if the unending calculations could be fully carried out, the results would be exactly the same in all cases. Furthermore, when he recalls that in the past the most difficult mathematical questions have been ultimately answered, he is inclined to believe with the great German mathematician, Hilbert, that every mathematical fact is provable. Besides all this, he attributes certain values to his results and their mathematical demonstrations: some theories seem important; some proofs are regarded as elegant, others as profound or original, etc.

Such somewhat vague ideas illustrate what I would call mathematical faith. Nearly all the greatest mathematicians have been led to take points of view falling in this broad category, and have attached the deepest significance to them.

What I wish to emphasize concerning this generally overlooked aspect of mathematical thought is that on one hand, the beliefs involved have been of the utmost heuristic importance as instruments of discovery, and, on the other hand, when examined in detail they generally turn out to involve ideas which are held true or false, according to the specific definitions which may be afterwards adopted.

Suppose, for example, that we turn to the first question of the existence of infinite classes. There was no question about the unconditional acceptance of such classes until within a few decades, although a few, like the ancient Greek philosopher Zeno and the German algebraist Kronecker, profoundly distrusted the use of the infinite in mathematical reasoning. To-day, however, due primarily to the theory of transfinite aggregates created by Georg Cantor about fifty years ago, mathematicians have come to realize that such an infinite class may exist in the so-called 'idealistic' sense but not in the sense of explicit constructibility. Thus the class of all collections of positive numbers less than 1 exists in the idealistic sense, but not in the alternative, more concrete sense.

A similar situation has arisen in the detailed study of the self-consistency of mathematics. It has appeared that very limited parts of mathematics can be proved self-consistent. But such a general assertion as that "the whole of mathematics is self-consistent" would be considered to-day not to be sufficiently precise; and each time that the proof of self-consistency is extended further, a definite logical price has to be paid in that certain so-called metamathematical ideas are tacitly employed, which need themselves to be investigated in the same respect. For example, the work on the foundations of logic by Whitehead and Russell (1910) showed that if the notion of class was not restricted, certain logical paradoxes would inevitably result. For this reason a theory of the 'hierarchy of types' was devised by them, which limited the notion of class and so avoided the apparent inconsistencies. We are thus entitled either to say that mathematics as of the year 1900 was self-consistent or was not, according to the point of view which is adopted. In any event the belief in question has led us to a much deeper insight into the nature of logic.

With regard to the unlimited power of mathematical demonstration, it has been recently proved by the Austrian mathematician Gödel that, if we restrict ourselves to reasoning of an ordinary

type, there exist explicit 'undecidable' theorems, while from a higher metamathematical point of view such a theorem might be demonstrable. Hence Hilbert's affirmation is in one sense false. But despite this fact, the open question on which he focused attention is much better understood than ever before.

Likewise in the question of value in mathematics, such as the importance of theories, or the elegance, profundity and originality of proofs, it is clear that these obscure ideas depend in large measure upon the momentary state of the science. Thus the theory of functions of an imaginary variable and classical geometry were regarded as extremely important a quarter of a century ago; while to-day the theory of functions of real variables and the basic kind of geometry called analysis situs have respectively displaced these subjects in general mathematical esteem. It would be hard to explain adequately the reasons for this change, but the increasing role of discontinuous quantity in physical theory and the relativistic point of view towards space and time have certainly been contributing factors.

An excellent instance of the power of individual mathematical faith in bringing about creative advance has been afforded by an American mathematician, the late Eliakim Hastings Moore. Moore was a thorough-going abstractionist who believed that mathematics itself should be reorganized from a still higher point of view by the dissection of essential common parts out of apparently different abstract fields. His point of view was strongly confirmed by the analytic work of Hilbert and Erhardt Schmidt near the beginning of this century. So Moore was led to create his 'general analysis' in 1906. This aimed at embodying his conviction that "The existence of analogies between the central features of various theories implies the existence of a general theory which underlies the particular theories, and unifies them with respect to these central features."

As time has elapsed, the deep truth of Moore's contention has been amply sustained. Indeed one of the most active schools of contemporaneous mathematical thought follows the higher abstract point of view adopted by Moore. But it has been found necessary to modify Moore's programme in that instead of a single 'general analysis' serving as an *omnium gatherum*, it has been desirable to employ a few typical forms. In this way his faith in the power of higher abstraction has been largely and yet not fully justified.

A good many mathematicians are seriously hampered by lack of the ardent positive faith which Moore showed. This type of deficiency is generally due to a strong development of purely critical powers and to over-specialization. Several times I have observed this lack in myself only to be counteracted by definite effort. For example, I did not make active use of the fundamental integral of Lebesgue for a long time, and so was prevented from pursuing to their natural conclusion certain ideas which finally led me to establish the basic 'ergodic theorem' in 1931. Here I was finally converted, as it were, to the use of this tool by the important advances of Koopman and von Neumann, and in particular by the latter's proof of the 'quasi-ergodic theorem'. It is worthy of note that the related ergodic hypothesis goes back in its origins to the physicists Boltzmann and Maxwell.

SPACE, TIME AND FORCE

Let us turn next to the physical level, where the corresponding situation is at least equally interesting.

If we accept the ordinary conceptions of space and time, which seem destined always to play a basic role in workaday physics, we find that the simplest physical ideas are those which arise through the manipulation of massive bodies. As these ideas have become clarified, they have been given abstract formulation in terms of such concepts as those of mass, force, etc. Newton's celebrated three fundamental laws of motion embody the final form of the refined intuitions thus arrived at. With these as a basis and the acceptance of certain further special observed laws, one may deduce by mathematical reasoning the theory of mechanics as applied, for example, in the solar system.

Similarly, through experimentation with electrified bodies, electric currents, magnets, etc., there was developed by Faraday the intuitive ideas of electric and magnetic lines of force which are now generally accepted. Later, Maxwell incorporated these ideas in the appropriate electromagnetic equations. Upon this basis all classical electromagnetic theory has been logically constructed. Furthermore, by means of the identification of the light wave and the electromagnetic wave, due to Maxwell, an adequate theory of light has been obtained.

Thus we see the important part which intuition and reason have played in two fundamental

branches of physics—mechanics and electromagnetism. A cursory survey of the various other branches of the subject would show that a similar situation holds throughout, except in the rapid developments of quantum mechanics during the last decade or so. In this strange theory the physicist begins indeed with a planetary model of the atom, reminiscent of Niels Bohr's earlier theory. But a flying leap is made from this temporary scaffolding to what is thenceforth regarded as the only basic reality—the wave equations of Schrödinger and, better still, of Dirac. Once having arrived at these mathematical equations, the physical theorist proceeds to show how he can predict innumerable facts previously out of his range by use of this arbitrary *ad hoc* machinery. The process involved somehow reminds me of a record sea voyage made through a fog!

The fact remains, however, that the recent development of quantum mechanics forms one of the most astounding and important chapters of all theoretical physics. It is interesting to recall how this great advance came about through the faith of the German physicist Planck at the outset of the present century. His direct experience with the phenomena of radiation had led him to believe that there were discontinuous processes at work, not to be explained by any modification of the time-worn classical theories, and so he was led to formulate his celebrated quantum hypothesis in 1900. It was this daring concept of Planck, more than anything else, that has freed the minds of physicists from the shackles of too conventional thinking about atomic phenomena, and so has made possible the quantum-mechanical quest, of which the end is not yet in sight.

There has always been an abundance of faith among the physicists. Everyone knows how Newton and others have found confirmation even for their religious beliefs in the lawful character of physical phenomena. It is not hard to understand why the tendency towards dogmatic affirmation among the physicists has been stronger than among the mathematicians. For the physicist, with considerable justice, feels that he is exploring the mysteries of the only actual and very exciting universe; whereas the mathematician often appears to live in a purely mental world of his own artificial construction. A good illustration of this tendency of the physicists is afforded by their changing attitudes towards the wave theory versus the corpuscular theory of light. Over a considerable period the corpuscular theory of Newton held

sway; then this was displaced by the wave theory of Huygens, the Dutch physicist; and nowadays a kind of vague, uncertain union of the two is generally accepted.

In this connexion it is especially interesting to recall the scientific beliefs to which Faraday was led in his fundamental work on electricity and magnetism. From his experimental results in this field, he saw that there was obeyed here as elsewhere the law which he called the 'conservation of force' and which we to-day would call the 'conservation of energy'. He saw that this energy was localized in space, and he could only conceive of it as being propagated in time; and so he was led to the belief that electromagnetic energy is also propagated with finite velocity. Thus in an article, "On the Conservation of Force," published in 1857, he expressed himself as follows: "The progress of the strict science of modern times has tended more and more to produce the conviction, that 'force [energy] can neither be created nor destroyed' . . ."; "time is growing up daily into importance as an element in the exercise of force; to inquire, therefore, whether power acting either at sensible or insensible distances always acts in time is not to be metaphysical." By way of justification of the rather mathematical direction in these thoughts, Faraday said further, "I do not perceive that a mathematical mind, simply as such, has any advantage over an equally acute mind not mathematical . . ."; "it could not of itself discover dynamical electricity nor electromagnetism nor even magneto-electricity, or even suggest them." But the achievements of the more mathematical Maxwell were later to show that Faraday had underestimated the power of pure reason.

It is thus clear that through an act of faith Faraday attained to a kind of deeper insight; for the existence of the electromagnetic wave has long since been established experimentally. However, the beliefs of Faraday in this connexion cannot be regarded as absolutely true, since according to present-day conceptions the notion of energy which he accepted is only roughly valid as a statistical approximation. Nevertheless, Faraday certainly penetrated more into the nature of electrical and magnetic phenomena than any of his contemporaries; and it is difficult to see how, with the limited mathematical and physical knowledge at his disposal, he could have gone any further in the way of prophetic conjecture.

The intimate relation between philosophical-

scientific points of view and actual advances in theoretical physics has been admirably illustrated by Einstein's gravitational theory of 1915. Taking as his starting point the bold but reasonable hypotheses that matter must condition space and time, and that, in parts of space remote from matter, elementary particles move with uniform velocity in a straight line, he arrived at his field equations as the most elegant mathematical embodiment of these ideas. Thus there was obtained a quasi-geometrical theory of gravitation which in certain respects is more natural than the celebrated theory of Newton, while the predicted differences, although excessively minute, are in favour of the new theory. But Einstein's theory cannot be regarded as true in any absolute sense since it gives us at best a partial, highly idealized view of the physical universe.

It is scarcely too much to say that, since the beginning of the present century, the main advances in theoretical physics have been the outcome of a similar kind of mathematical guesswork, in which, however, the mathematician himself has taken little or no part! The guessing of the physical theorist is guided almost entirely by considerations of subtle mathematical analogy.

In my own limited experience in mathematical physics I have seen how natural it is to take a positive attitude on open questions. Thus a good many years ago I showed mathematically that mere spatial symmetry about a centre necessitates a *static* gravitational field. This led me to believe that the Einstein field equations were probably too inelastic to fit the facts, but I did not put forth this opinion. Shortly afterwards Lemaitre, in trying to explain the expanding (non-static) stellar universe, found it necessary to modify the field equations, in part because of my result; and so my belief was to this extent justified.

Again, I have had during the last few years a feeling that a conceptual space-time model for quantum mechanics is likely to be found, although theoretical physicists would in general disagree. Nevertheless, this faith is so strong that my recent researches lie principally in this direction. I have already found interesting results, and feel confident that these efforts will not be wasted, since the possibilities of the conceptual approach need to be more carefully explored.

In ending these remarks about the role of intuition, reason, and particularly of faith, at the physical level, it is to be remarked that the physicist

as such systematically ignores the phenomena of life, for it is inorganic and not living matter with which he concerns himself in his laboratory.

All in all, it is a faith in the uniformity of Nature which remains the guiding star of the physicist, just as for the mathematician it is a faith in the self-consistency of all mathematical abstractions, although these faiths are more sophisticated than ever before.

INTUITION IN THE BIOLOGICAL FIELD

Although I have no especial acquaintance with the biological, psychological or social domains, it seems clear to me that a similar situation prevails in them. In the biological field the intuitions upon which one depends are those associated with the concept of the organism and its evolution. These intuitions cannot be formulated conclusively and completely in simple postulates, as is possible at the mathematical and physical levels. It is rather through an acquaintance with an immense array of interrelated, analogous facts that the biologist finds himself able to deal with novel situations. By means of the geological record on one hand, and the results obtained in the field and laboratory on the other, he acquires a better and better understanding. His principal weapon is always inductive reasoning. It seems certain that a deductive treatment of biology is at least very remote, and if ever accomplished will be utterly different from anything which we can imagine to-day. There are, however, a few special fields like the theory of heredity, in which a considerable mathematical structure has been developed. In this theory, by means of the chromosomes and their corresponding abstract genes, it has been possible to explain a complicated array of facts.

The faith of the biologist generally tends in the direction of a mechanistic theory of life or of some opposing vitalistic theory. In fact, he is forced to employ the principle of physical causation in his efforts to understand biological phenomena and does not yet know of definite limitations in its use. Recently there has been some indication of a return to vitalism, so that once more a considerable group of biologists are convinced that not all the phenomena of living matter are to be accounted for by ordinary physical and chemical law. The controversy involved has long been a burning one, and accordingly one naturally suspects that the question is really meaningless. In any event, however, special mechanistic

hypotheses have so far pointed the way to new creative advances.

It is interesting to remark that the insufficiency of a rigorously deterministic theory of the living organism admits almost of mathematical demonstration in the following manner. A genuinely mechanistic universe would have to be free of any infinite factors. For example, if one accepts a simple Newtonian theory, there might be reaching the earth from infinite space unknown quantities of matter and energy, so as to change arbitrarily the course of events upon the earth. But in any completely mechanistic system, free of such infinite factors, it is not difficult to prove that there will necessarily be a kind of eternal Nietzschean recurrence. For example, we are here together this evening considering a particular topic. The strict adherence to the deterministic point of view would entail the consequence that in the eons yet to come this same scene will be re-enacted infinitely often. I submit that this is dramatically improbable!

Recent advances in the chemical knowledge of large organic molecules seem to indicate an innate hospitality of actual matter toward the evolution of the living organism. In this way a plausible genetic account of the origin of life is suggested, which, however, can scarcely be called mechanistic. It begins to seem possible that we are on the verge of further refinements in our concept of matter, such as Emerson anticipated in the quotation made above.

The situation at the psychological level is even less amenable to precise treatment. All of us have a lifelong experience with ourselves and other human beings. This automatically gives rise to a vast complex of intuitive psychological notions. We all are aware of course that there are concomitant physiological processes going on in the body, nervous system and brain. Now it is the business of the professional psychologist to give exact definition and interpretation to these crude ideas; and he finds his greatest illumination in the facts of abnormal psychology, with which most of us are unacquainted. However, in the case of either layman or professional, the processes of reasoning are mainly by analogy. Even the psychiatrist, familiar with many concrete cases, must treat each new patient by the inductive method. There are too many psychological intuitions and too few exact laws for any imposing edifice of pure reason to be erected.

In certain restricted psychological domains,

formalization is to some extent possible. Thus I have ventured to formulate a theory of 'aesthetic measure', by explicit numeration and weighting of aesthetic factors. This aims to explain certain simple aesthetic facts in our enjoyment of visual and auditory forms. The theory has been to some extent substantiated by experiments made at Harvard and elsewhere. But in any event, no matter how successful the theory might prove, it would be wholly absurd to try to set up an elaborate logical structure on the basis of the fairly arbitrary and inexact assumptions involved. Generally speaking, as we proceed from the more objective to the more subjective levels of thought, we find that elaborate logical structures seem to be of less and less utility.

The basic belief of the professional psychologist is in the completeness of the physiological accompaniment of every psychical fact; and he formalizes the observed facts by means of this parallelism. But there is a conflict between this attitude of the technician towards mind, for whom the individual is a complex of neurally characterized components, and that of the ordinary man—equally an expert though of a different kind—who sees all sorts of permanent values in personality, not adequately characterized in neural terms. The second attitude leads nearly all of us to have deep affections and abiding personal loyalties, whether or not we are psychologists!

Here again I think that these apparently opposing points of view are both more or less true; and I incline all the more to this opinion because of my conviction that as yet we know relatively little about the phenomena of personality. For it seems certain to me that the extent of hidden organization in our universe is infinite, outside as well as inside space and time; such a conviction is very natural to a mathematician, since the three ordinary spatial dimensions and the single temporal dimension are for him only particular instances of infinitely many other conceivable dimensions! If this be true, any broad conclusions concerning the nature of personality would seem altogether premature.

At the social level the most serviceable intuitive ideas cluster around the concept of societal evolution. It is of course the comparative study of human institutions which furnishes the principal interest. The analogy between forms of society and evolving organisms is a deep-lying one. Here again the useful logical structure which can be built around the very complicated facts is exceedingly

simple. Even in such a formalized field as ethics, dealing with the behaviour of the individual as a member of society, logic takes an almost negligible role.

Belief here seems to gather principally around the idea of societal progress. Progress—or its non-existence—serves as our fundamental tenet. Some believe that society can improve indefinitely, tending toward a perfect society. Such a belief is of course a fundamental one in most religious systems. Others find this idea too naive. They stress the gregarious instinct in man and tend to think of societal changes as taking place in various directions strongly conditioned by changing physical environment. All would admit, however, that without the concept of dynamical social processes, social theorizing would be stale and unprofitable.

SCIENCE AND SOCIETY

Let us turn now to consider some further conclusions, towards which this brief survey of intuition, reason and faith at the various levels seems to point.

So far as intuition and reason are concerned, these are the common property of all competent individuals. The narrow, closely articulated chains of deductive reasoning serviceable at the earlier levels are more and more replaced by loose webs of inductive reasoning at the later levels, as we pass from the objective to the subjective. At the same time the basic intuitions change from the simple and precise types employed in mathematics and physics to the increasingly complicated and diverse forms characteristic of biological, psychological and social phenomena.

However, it is just as necessary to clarify and to formalize our knowledge at these later levels as at the simpler ones. The processes of systematic reasoning, whether inductive or deductive, have always a definite prophylactic value, and in particular enable us to avoid the dangers of prejudiced and intolerant points of view. It may be observed in passing that the careful application of impartial thoroughgoing analysis is as important for everyday living as it is in the study and the laboratory.

The striving for rational comprehension is one of the noblest attributes of man. In his age-long difficult struggle he has been able to secure greater freedom only through a better technical mastery of his environment. No other method of liberation has been vouchsafed to him. But this increased

mastery has brought with it automatically new intellectual responsibilities and a more complex way of life. In consequence, unforeseen and threatening dangers arise from time to time; and there is thus imposed on him the necessity to advance still farther, which is to-day more urgent than ever before. A new injunction has been laid upon the spirit of man, to know and to understand ever more broadly and deeply.

Now along with the increase in scientific knowledge there appear certain crudely expressed, deeper insights, not completely true or false, some in opposition to others, but all supremely valuable, nevertheless. These are embodied in beliefs which seem the inevitable accompaniment of all creative thought.

Thus in the daring effort of the scientist to extend knowledge as far as possible, there arises an aura of faith. It is this spontaneous faith which furnishes the most powerful incentive and is the best guide to further progress.

Such are some of the very general points of view to which a considerable mathematical and scientific experience has led me. If they are worthy of serious attention it is not because of their novelty, but rather because in their aggregate they rise above the details of the numerous specialized fields of knowledge and sustain the scientist in his unceasing and ardent search after truth.

Doubtless many will be ready to ask the ever more insistent question: If science has thus profoundly modified the general outlook and way of life of mankind, is it not the especial duty of such an association as ours to point out constructive remedies for the ensuing maladjustments? In "Part II; Science and Warfare" of his admirable address as president of the British Association last August, Lord Rayleigh closed by expressing the hope that our two associations could co-operate in such a way as to "bear useful if modest fruit in promoting international amity". In this hope all of us will deeply concur. The presence of Sir Richard Gregory among us at this meeting is the first token of the projected closer relations between the parent British Association and ourselves. It is much to be desired that this action will encourage further unification of the whole scientific world. I am sure that practically all our joint membership would agree with me that it is the wider diffusion of "the steady light of scientific truth" which holds out most hope of a better understanding among men.

Religion in Science*

By Sir Richard Gregory, Bart., F.R.S.

IF religion be understood in the broadest sense as the belief in spiritual being, it may be said that prolonged inquiry has failed to show any authenticated instance of a people, however backward, who do not hold to some form of belief which, though vague and rudimentary, can be deemed religious. It is difficult to draw a hard and fast line between magic and religion; and indeed it is a question whether such a differentiation is essential from the point of view of the inquirer who is attempting to trace the development of the religious idea. For even 'magic' implies some form of spiritual influence humanly directed. Belief in the efficacy of magic is as much an act of faith in some form of spiritual action as the Christian belief in Divine intervention in human affairs; and the essence of a religious belief is that it is an act of faith.

Faith may be defined as a belief which is not dependant upon material evidence or logical demonstration from premises ultimately based upon sensory phenomena (although such phenomena may be invoked to support faith as 'proof'); but it acquires its validity from some general scheme or theory of the nature and purpose of 'being', 'life', the universe, or, as the philosopher would say, of 'the Absolute', or, to use a popular phrase, 'the scheme of things'. In essence it is emotional: not rational. In its contact with 'facts', faith interprets them not by observation and experiment—that is by the approach of reason and science, which demand proof in the strict logical sense, by reference to phenomena—but it evaluates them by the test of coherence with its theory of life and the universe. Such a scheme need not necessarily be consciously formulated or even realized as a whole. Probably, in the early phases of development, such realization rarely, if ever, takes place, as the minds of backward peoples work concretely and are averse from abstraction.

Whatever may be thought of evolutionary faith, evidence from comparative study shows that there is, in the mentality of man, a generalized urge towards a belief in spiritual values underlying the material appearances of the universe. This urge is fundamental. Various influences such as the influence of geographical and cultural environment, and possibly mental differences of racial strains, if there are such, have combined to produce

the different types of belief and the religious systems which have been followed, or are now followed, by mankind. It is at least significant that in the so-called primitive religions of the less advanced cultures there should be such strikingly close similarities in ritual and belief as have been recorded by the anthropologist. Further, when we try to attain an objective view of the more advanced religions, it is no less striking that they fall into a more or less uniform pattern in regard to the relation of the three elements—tradition, ritual and ethics; in other words, in the relation of belief to worship and the conduct of life. Dissension arises not so much out of the nature of tradition as when interpretation is added to it and made a test of orthodoxy. When there is a difference in the central objects of the various cults, opportunities for dissension are multiplied and reconciliation might seem wellnigh impossible.

RELIGION AND LIFE

Many reasons have been put forward to account for the origin of religion, but it cannot be said that any of them has solved the problem. Ancestor-worship, ghost-propitiation, worship of the soul, belief in spiritual beings, reverence for tribal leaders, and other causes, have all been suggested as originating causes of religious sentiment. Primitive man had no religion, except such as was embodied in a system of social virtues. Men possessing these virtues to a high degree, and using them to make the tribe powerful or conditions of life more pleasant, would be esteemed as benefactors or heroes not only during life but also after death, and this veneration would develop into ancestor worship and later into soul worship.

If it is assumed that the Divine purpose of the existence and evolution of life upon the earth is that man should work out his own salvation, it is difficult to understand what the ultimate gain will be when the earth will no longer be in a condition to maintain life as we conceive of it. All that science can say as to the future of the earth or any other planet or system in the astronomical universe, is expressed in the words of the hymn "Our little systems have their day: they have their day and cease to be". We may contemplate the progressive development of man and society to whatever stage may satisfy our ideals, but, so far as we now know, the whole phantasmagoria will eventually

* From a public lecture delivered before the American Association for the Advancement of Science meeting at Richmond, Va., on December 27 1938.

be dissolved, and the death of mankind will be the final penalty for achieving the highest type conceived by the human mind. This thought should not, however, be subversive of effort and aspiration on the part of humanity as a whole, any more than the individual should neglect noble motive and conduct because he himself has to pass away whether his influence has been for good or evil. Though science is unable to provide any positive evidence for survival of personality after death, it must acknowledge that belief in such survival is a powerful ethical factor in human development.

Evidence of the progressive development of forms of life in the past, and of changes still going on, is so convincing that it may almost be regarded as a law of Nature. In so far, therefore, as evolution signifies an orderly succession of organic growth, few would venture to deny the fact; but how and why such changes are brought about has not yet been established beyond discussion. Whether organic evolution has proceeded by gradual development of small variations of structure and habits, or by the sudden appearance of new forms, is a question for naturalists to decide among themselves in their search for natural causes. The govt of observational science is concerned only with evidence which throws light upon such causes and effects without assuming the existence of supernatural design or intervention. Whether behind the natural causes producing evolution there is a transcendental principle or architect is not the concern of naturalists, but of other philosophers. Their position is that even if the facts of organic evolution cannot be explained by existing knowledge, they will be explicable when more is known about natural causes and consequences, without introducing a *deus ex machina* to conceal our ignorance and suppress the pursuit of objective evidence.

We have passed the stage when, in order to afford support for Christian belief in general, and the Mosaic account of creation in particular, it was only necessary to find naturalistic or rationalistic explanations of miraculous and other elements in Biblical records. Such attempts to fit all new knowledge into a system of thought having no claims to scientific accuracy or intantion served no useful purpose to the Bible or to science, and to-day would satisfy neither historical students nor naturalists. A much sounder basis can be found by applying evolutionary principles to religious thought, and by studying sacred books as stages in the story of man's progressive discovery in theology. It is only by disregarding history that the idea of a fixed and final theology becomes possible. In science, there are no final interpretations or unchangeable hypotheses; and if the

same principle were recognized in theology, religion would share some of the vitality of the natural sciences. Evolution can be regarded by the theologian as merely the means of creation; and this conception of gradual development is not incompatible with Christian theology. It is through the acceptance of the idea of evolution in the spirit as well as in the body of man that the partition which formerly separated religion and science is being dissolved.

All religions—primitive and advanced—include ethical ideals relating to human conduct and its supreme end. The highest form of religious ethic is that in which the aim of conduct is complete and implicit obedience to a code which is conceived as the will of God. In the less generous manifestations, this obedience may be rendered against natural inclination as an outcome of fear; for "Fear of the Lord is the beginning of wisdom." It may then degenerate into a formalism as lifeless, and even more harsh, than that of those systems which stress ceremonial purity. On the other hand, it may become a joyous and spontaneous acceptance of a mode of life, such as it is conceived would be consonant with the nature of God, subject to such limitations of the flesh as are ineradicable—the idea of saintliness. Hence arises the desire for uprightness as an end in itself, either with a view to reward, if not in this world, in another; or pursued selflessly for its own sake. This concept of religious ethic, which rests ultimately on personal and intimate relationship between the individual soul and its God, has led to the highest idealism in human conduct; but it has also degenerated into many unpleasant forms of exaggerated and distorted continence and self-torture in the monastic, ascetic and mystic conceptions of the holy life.

SCIENCE AND SOCIAL ETHICS

In recent years, there has been much discussion of the ethical or social consequences of the application of mechanical and other scientific discoveries to industry. In the early days of the industrial revolution in England, there was little of the scientific spirit in industry. The discoveries of science were used with as much indifference to science as to humanity. The inventions of the eighteenth and early nineteenth centuries came from the workshop rather than from the scientific laboratory. Machines were devised and operations developed largely by trial and error methods, and academic research had few points of contact with industrial practice. The characteristic of the present age is the utilization in industry of principles, properties, and products revealed by scientific research, whether carried on solely in the pursuit of knowledge or with a practical purpose in mind.

It is sometimes suggested that progressive science and invention are responsible for the troubled condition of the world at the present time, owing largely to over-production. It would be just as reasonable to blame the Almighty for good harvests, or for providing in some parts of the world all the means of existence for primitive man without the need for labour. The fault is not with those who create gifts for men's comfort and enjoyment, but with the social system which prevents their easy distribution and use.

Material progress must be more striking, more patent to observation than is man's ethical and social development; and it is also no more than to be expected that there should be a lag in the latter. It was more than a generation after the initial movement of the industrial revolution in Britain that progress in other directions began to affect the population of the country at large. To anyone who takes long views and compares conditions of to-day with those of a hundred to a hundred and fifty years ago, it must appear a rash statement which characterizes man's progress in that period as one of command over the material resources of the world only. This is to deny certain patent facts. For example, in every department of human life—at any rate, in Great Britain—there has been in that period a stupendous awakening to a sense of social responsibility—a very real development in man's mentality and the growth of society. In effect, it now demands that the latest results of all branches of scientific research, but more especially of those affecting hygiene, both physical and mental, should be applied to the conditions of life of the population as a whole. This is not philanthropy or religion as such in the narrow sense, but arises from a broadening in the conception of the relations and obligations of man to man.

Apart from the mental and moral effect, difficult to gauge, of improved conditions of life, the increased application of the results of scientific research to those conditions has been accompanied by a parallel growth in the sense of responsibility in the community towards every member of that community—the concept that of the wealth of the community a toll must be taken to ensure that from the cradle to the grave each individual member shall be ensured a certain measure of healthy nourishment, opportunity for growth in body and adequate instruction in mind by education to become a useful member of the community, with assurance of medical attention in employment, of a measure of sustenance to the unemployed and of provision for old age.

This is not communism, unless it be communism to admit that I am my brother's keeper; but it is precisely towards this admission that practical

application of the modern science of man is directing mankind, both as an inference from the study of societies of the past and the humbler societies of to-day among primitive peoples, as well as from a diagnosis of the elements which appear to make for progress in modern civilization. It is true that a modern society with a sense of responsibility, but which, it must be admitted, we have not yet fully attained, is only now approaching the position of the primitive group in its sense of responsibility to its members; but the advance, the spiritual progression, lies in the range of that sense of responsibility. Whereas in the primitive form it embraces the members of the blood kin only, or those of the local group within which the members are more or less intimately acquainted, within a modern society it may reach out to embrace all members of a great nation, and possibly, when warring creeds agree to sink their differences, it may extend to all men of good will, to whom the dignity of man as an individual entity transcends racial and political boundaries. When, if ever, that comes to pass, it will be possible to gauge how far man has advanced along the road of ethical as well as material progress.

To many, the way seems long to go. The urge of nationalism and its ideals has diverted the thoughts of peoples—both Fascist and Communist—away from the main stream of human progress into narrower channels in which rocks and rapids threaten at every turn to shipwreck all that is best in civilization. The result is that instead of science having to save modern civilization from being overwhelmed by barbarous hordes, it seems to have provided the means of self-destruction. Man has advanced so little in spiritual evolution that he is just as much a barbarian in his use of aerial bombs and poison gas as he was when his weapons were only clubs and arrows.

Such prostitution of the rich gifts with which modern science has endowed the human race must be condemned by all who see, in the general feelings of civilized people to-day, incipient stages in the development of characteristics which distinguish man from other living creatures. The law of the jungle is that of the battle to the strong, and the race to the swift. It recognizes no right to live except by might; destroys the weak; has no sympathy with suffering; and no sense of the highest human values. In the struggle for existence, man has survived because his physical structure and intelligence have enabled him, individually and in communities, to master the things which would destroy him. His social instincts have at the same time been extended from the family to the tribe, the nation and the empire, and will reach their highest and best when they embrace the world.

that their names may be registered, and at the same time enclosing a remittance of one guinea, which will cover fifty telephone inquiries.

Association of Women Science Teachers

THE annual meeting of the Association of Women Science Teachers was held at Bedford College, London, on January 4 and 5. At the evening meeting, Prof. Allan Ferguson, lecturing on eighteenth century physics, stressed the value of the research of that century's Gargantuans in science, some interesting points of detail not always being known to present-day teachers. At the morning session, the Joint Standing Committee with the Association of Assistant Mistresses (Science Panel) presented its recent General Science Examination Syllabus, containing the maximum of content and topic for examination in general science after a five-year course to school certificate standard in girls' schools. Copies of this syllabus can be obtained on application to the Hon. General Secretary. A discussion was held on new methods of biology teaching, emphasising practical problems with living organisms. Both plants and animals were discussed. It appeared there is less need for the keeping of animals in the school, except occasionally, when the biology is taught from the functional view-point and with reference specially to the mammal. Discussion ensued as to whether there may be consequent application or lack of it, in the pupil's mind, to man. The study of the characteristics of living things based upon exact observational work on plants and animals in school appears to present more practical difficulties in the keeping of living creatures in captivity. Opportunities for visiting a glass factory and a precious metals refinery were welcomed by members. It is announced that the Association proposes to devote a whole day's discussion on March 4, in London, to the Science Masters' Association General Science Report and to the Spens Report in its bearing upon science in the curriculum.

Chinese Red Cross and Chinese Universities

MRS. HALDANE, who has recently returned to London after a visit to China, writes as follows: "I paid a visit to the training centre established by the Chinese Red Cross Medical Commission. This Centre is under the direction of Dr. Robert Lim, formerly professor of physiology in the National University of Peiping. Dr. Lim has temporarily given up his scientific work and has taken in charge the reorganisation and extension of the Chinese Red Cross. . . . In Kunning, formerly known as Yunnan Fu, I had the pleasure of meeting President Chiang, formerly of the National University of Peiping, and his staff; and also President Mei of Tsing Hua University, Peiping, and his colleagues. . . . Premises have been placed at the disposal of the universities by the Yunnan Provincial Government, but although they still have remnants of their former libraries, there is an almost complete dearth of equipment, scientific instruments and other material. The two Presidents and the professors of pure and

applied engineering and biology informed me that they would be deeply grateful if their colleagues in Europe could send them copies of current periodicals, such as the *Proceedings of the Royal Society*, the *Journal of Physiology* and *Biochemical Journal*, physical and engineering journals, etc. If members of the various scientific societies in Great Britain would care to assist either the Chinese Red Cross Society, or Prof. Chiang and Prof. Mei and their staffs, I should be most grateful if they would communicate with me, c/o The China Campaign Committee, Parliament Mansions, Orchard Street, S.W.1. The Committee would be glad to make arrangements to forward either periodicals or money, and to put British scientific or university circles in touch with their Chinese colleagues who at present so badly need their moral encouragement and active assistance."

Earth Tremor at Quetta

ON January 6 at 4h. 43m. (Madras Time), an earth tremor of considerable intensity shook Quetta, in Baluchistan. The shock was of short duration and no damage or casualties are reported. It will be remembered that this district is liable to be visited fairly frequently by earthquakes and that it was visited by a particularly strong one on May 31, 1935, of duration about 30 seconds and having an epicentral tract 68 miles long and 16 miles wide in a direction S. 15° W. from Balali. The epicentre was stated by Sen and Bakshi to be lat. 30° 5' N., long. 66° 5' E., and although the intensity was 10 on the Rossi-Forel scale, road and rail communications were not interrupted, nor was the supply of electric current, so that the intensity was not so great as at Assam in 1897, Kangar in 1905, or Bihar in 1934. No fault movement was apparent at the surface, and as the intensity fell off rapidly from the central region, the focal depth was assumed to be shallow. On that occasion, Kalat, Mastung, several villages and Quetta itself were completely destroyed, and Quetta was sealed for a considerable period owing to the extreme difficulty of the rescue work. The death roll was estimated at 15,000-20,000. The buildings of the new Quetta are of reinforced concrete and brick, and some attention has been paid to earthquake-proof design. They have withstood well the shocks of September and October 1937 and the present earthquake.

Roads and Traffic

IN his presidential address on "Roads and Traffic" to the Junior Institution of Engineers on December 9, Sir Charles Brossy raised many interesting questions the answers to which are not easily found out. He says, for example, that deductions from the most careful traffic observations are apt to be stultified, at any rate in a free country like Great Britain, by the essential fluidity and waywardness of traffic. The installation of traffic lights may lead drivers to make use of hitherto unfrequented side roads, so as to avoid the signals. These vagaries vitiate comparisons, and are particularly disconcerting in

London, where so many alternative streets are available for an intelligent driver. In addition, the science of mechanical engineering advances so rapidly that steep road gradients which render a road unpopular at present may in ten years time offer practically no hindrance to a motor-car. Any attempt to replan an ancient capital must be largely empirical; opportunism must play a leading part. The inertia of habit is a powerful force. Theoretical considerations have to be tempered by common sense based on a general knowledge of London's development and of the improvements which have been carried out or rejected during past years. However carefully the flow of traffic be recorded, we are still at a loss to account for the underlying causes of the waywardness. The mysterious flittings of trade and industry influence the distribution of the nation's population. The advantages of undeviating directness over great distances, unhesitatingly accepted by the Roman road engineers, who were untrammelled by county boundaries and ring fences around estates, would not be accepted implicitly to-day.

Archæological Discoveries on Monte Alban, Mexico

EXCAVATION of the Mixteco-Zapotecan necropolis on Monte Alban, near Oaxaca, Mexico, which has been in progress under the direction of Dr. Alfonso Caso without interruption since 1932, has produced a remarkable assemblage of objects, ornamental and ceremonial, in gold, semi-precious stone, or other material, illustrating the religion, life and customs of these peoples. In large measure the remarkable character of the finds justifies the dictum of the excavator that in the archæological sense this is the most important region in the whole of the Americas, not even excepting the Peruvian site of Cuzco. When one hundred and two tombs had been explored, the site was visited in the course of the past year by General L. Cardenas, President of the Republic. The occasion was marked by the opening of three further tombs, which the President, accompanied by Señor Caso, was the first to enter. The first tomb offered little calling for comment, but the second and third afforded the unexpectedly important and spectacular discovery of series of vivid polychrome frescoes adorning the walls. These depict gods and their symbols, as well as priests in ceremonial garb, sacred and mythological motives, and ritualistic symbols of life and death. In the third tomb, painted figurines were standing in ritual niches, and on the floor was a skeleton, obviously of a great chief, surrounded by a number of funerary objects, axes and knives in obsidian and flint, a green jade statuette of Quetzalcoatl, the Plumed Serpent of the Zapotecs, and a number of domestic and liturgical vessels. The mural decoration is considered to be the most important discovery yet made on Monte Alban. The President was so strongly impressed by the importance of the excavation that not only did he promise a Government subvention in order that the work might be continued, but also ordered an immediate grant of 10,000 piastres (approximately 60,000 francs). A brief account of the discovery and of the frescoes and contents of the tombs by Dr. Núñez y Domínguez,

secretary of the National Museum of Mexico, has recently appeared (*J. Soc. des Americanistes*, N.S., 29, 2).

Insects of Cambridgeshire

A LIMITED number of copies of the "Zoology of Cambridgeshire", the major part of which is occupied by the account of the Insecta, are now available. They are reprinted from the "Victoria County History of Cambridgeshire and the Isle of Ely", vol. 1, pp. 77-245 (1938), reviewed elsewhere in this issue (p. 46). Applications for these reprints, accompanied by a remittance of £1 ls., which covers postage, should be made to the editor, Dr. A. D. Imms, Zoological Laboratory, Cambridge.

Announcements

DR. R. L. SMITH-ROSE has been appointed, as from January 1, superintendent of the Radio Department of the National Physical Laboratory, which includes the Radio Research Station at Slough in addition to the section of the Department at Teddington. Dr. Smith-Rose has been principal scientific officer-in-charge of the Departments since Mr. Watson Watt left the Laboratory in 1936 to take up a position in the Air Ministry.

A BIBLIOGRAPHY on the housing and equipment of school libraries, compiled by Ellen L. Anderson, has been issued by the Office of Education, United States Department of the Interior. The bibliography consists of an annotated and selected list of references intended to show what schools have done for their libraries and to give concrete suggestions to those interested in starting a school library or in improving an old one. The list is limited to the physical aspects of the library and administration.

IN NATURE of December 24, p. 1130, in an article on "Future Developments in Coal Treatment and Utilisation", reference was made to a paper by Prof. A. O. G. Egerton and to experimental work described by Mr. Armstrong. Mr. Armstrong was said to be a research student from South Africa. We are informed that this is incorrect; Mr. Armstrong is from New Zealand.

THE National Research Council of Canada, Ottawa, announces the forthcoming publication in book form of a scientific account of a comprehensive study on the effect of sulphur dioxide on vegetation. The book covers an investigation carried out under the auspices of the National Research Council during the period 1929-38 on the effect on vegetation in Northern Stevens County, Washington, of sulphur dioxide from the large metallurgical plant at Trail, B.C., and also elaborate experiments planned to elucidate the many questions which arose in connection with the investigation.

ERRATUM.—NATURE, January 7, p. 34, article entitled "Structure of Proteins", col. 2, paragraph 2, last line, for "marked" read "masked".

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

Patterson Diagrams in Crystal Analysis

LETTERS on the interpretation of Patterson Fourier syntheses (vector maps) have recently appeared in NATURE^{1,2,3}. Is not the claim made or implied in these letters, that a new method of interpretation has been discovered, due to a misapprehension concerning the existing methods of crystal analysis?

What may be termed the classical method of crystal analysis, which has successfully elucidated numerous structures, is briefly as follows. Observations are made of the intensities of a number of X-ray spectra or reflections from crystal planes. The unit cell and symmetry scheme of the crystal is determined, and the composition and density of the crystal indicate the number of atoms of each kind in the unit cell. The efficiency with which the individual atoms scatter X-rays through various angles can be deduced from the known distribution of electron density around each atomic centre. The investigator then has the problem of adjusting the positions of the atoms in the unit cell until he hits on an arrangement which explains the intensities of the observed spectra. The atomic positions are fixed by a finite number of co-ordinates (parameters) and it is his task to assign values to these parameters. Given a sufficiently extensive set of observations of intensities, no reasonable doubt can be entertained that a solution which explains these observations is unique.

In the second paragraph of his letter², Prof. E. H. Neville outlines an argument which purports to demonstrate that substantial reconstruction of the crystal structure is theoretically impossible, since the observations may correspond to an infinity of solutions, and then proceeds to combat this view. I do not know from what source he got the impression that such a view has ever been expressed or could possibly be held by anyone who is acquainted with the methods of crystal analysis. If the distribution of scattering matter within the unit cell could have any general form, the problem would of course be indeterminate; but in actual fact we know the scattering matter to be clustered in a characteristic way around a finite number of atomic centres; this makes the solution unique. This has been the basis of crystal analysis for the last twenty-five years, and is so well known that it is generally taken for granted and not specifically referred to in recent work, which perhaps explains how Prof. Neville's misapprehension has arisen.

The elegant Fourier series methods now so widely used have been summarized in the recent letters, and need only be very briefly outlined here. The distribution of scattering matter in the crystal cell may be represented by the sum of a three-dimensional Fourier series. X-ray measurements determine the amplitudes of the terms of this series, but not the

phases. Hence the observations do not lead directly to a solution by straightforward Fourier summation. The problem is simplified by the fact that in most cases one is dealing with a projection of the structure which has centres of symmetry. In such a case the uncertainty of phase reduces to one of plus or minus sign, since each term must have a crest or a trough at each centre of symmetry. A common method of procedure is to get by trial and error a first approximation to the structure which decides the signs of the more important Fourier terms, and then by summing the Fourier series with these terms to get a better idea of the atomic distribution, which enables more signs in turn to be fixed. Two or three such stages of approximation complete the structural determination. In special cases, other methods of fixing the signs can be used. The basis of this procedure is again our knowledge that the scattering matter is concentrated around a finite number of atomic centres as explained above.

The Patterson synthesis⁴ or vector map does not demand a knowledge of phases, because the coefficients of its Fourier series are proportional to measured intensities, not amplitudes. The density in a Patterson projection at the end of a vector drawn from the origin represents the integration over the unit cell of the product of densities at all pairs of points in the crystal structure which have that vector relationship. Patterson sections can also be constructed.

Since a Patterson diagram can be directly constructed from the observations and summarizes all the measurements in a graphic way, it has certain very attractive features. It is a comparatively novel method, and it is highly important to explore ways of using it to deduce the crystal structure. Papers by Beevers and Schwartz⁵, Lipson⁶, Gaskell⁷, Goodwin and Hardy⁸ and Wells⁹ may be quoted as examples where it has already been successfully employed. In most of these cases there are certain outstandingly heavy atoms in the crystal structure, and the relative positions of these atoms can be deduced from the positions of peaks in the Patterson diagram. These heavy atoms are so important in fixing the signs of the Fourier terms that the analysis can then be completed. The 'geometrical method' proposed by Wrinch, which Prof. Neville claims 'has opened a new chapter in crystal analysis', is essentially the same as that used in these and other investigations.

Experience with Patterson diagrams brings home to one, however, the very great difficulty of interpreting them owing to their complexity. Dr. Wrinch gives an example¹⁰ of the relation between point diagram and vector diagram to show how the first can be deduced from the second, but the idealized case she takes is so extremely simple that any method of analysis would immediately succeed. If we compare the density distribution (point diagram) and

Patterson (vector diagram) for a moderately complex case such as an aromatic molecule, it is quite difficult to trace the relationship even when the structure has been determined and we know the answer to the problem set by the Patterson. Not only the relative positions within the molecule, but also those of atoms in neighbouring molecules related by the symmetry elements, are represented by superimposed diffuse peaks in the Patterson, and these combine in such a way that it is extremely hard to unravel the tangle.

The molecule of a protein such as insulin, for which Crowfoot¹ gives Patterson diagrams, is of a much higher order of complexity than an aromatic molecule containing a few benzene rings; it is far beyond anything as yet analysed by X-rays. Experience with the difficulty of interpreting the Patterson of simpler molecules warns us to be extremely cautious in basing conclusions upon the diagram of insulin. I would not venture to suggest that analysis is a hopeless task; on the contrary, there is every hope of ultimate success, for aromatic molecules seemed hopeless problems not many years ago, and their analysis is now almost a matter of routine. I would plead, however, for a due sense of proportion. Langmuir and Wrinch claim that the main features of the Crowfoot diagram can be explained by a certain concentration of scattering matter in a simple way at a few typical points in the molecule. If this claim is substantiated, it affords a useful hint as to one possible solution; but whether it is unique depends, as in all cases of X-ray analysis, on the justification for the assumptions which are made. In simple structures, we are on sure ground, for we know the scattering units to be a finite number of atoms. In a protein, the assumptions must as yet be vague and provisional. Exaggerated claims as to the novelty of the geometrical method of approach and the certainty with which a proposed detailed model is confirmed are only too likely, at this stage, to bring discredit upon the patient work which has placed the analysis of simpler structures upon a sure foundation.

Vector Maps and the Cyclol Hypothesis

IN recent issues of NATURE, letters have appeared in which claims of a new method of analysis of Patterson vector diagrams are put forward with particular reference to those of crystalline insulin¹. Substantially this method is not new to crystallographers; it is implied in Patterson's original paper in 1934², has been used in a number of published analyses³, and has been taught to students in Cambridge for the past three years.

What is new, however, is the use of certain additional assumptions and their application to cases

where they are of extremely dubious validity. Thus the substitution, suggested in Prof. E. H. Neville's letter, of points for peaks in the Patterson vector map, and the subsequent attempt to find a point system to which this vector map corresponds, is not a reliable procedure in the analysis of complex crystals. The maxima in the vector map can only be assumed to correspond in position to steps between regions for which the electronic density ρ is a maximum if the maxima of ρ are sharp and the vectors between them are distinguishably different. While these conditions hold for simple structures where each peak stands for one atom, they cannot be assumed to do so for compounds as complicated as the proteins and here, therefore, much greater caution would seem to be required. Even if, however, we make this simplifying assumption and are prepared to treat as a geometrical point a group which we know to be composed of some hundred atoms, far greater ambiguity exists than might be imagined from reading Dr. D. M. Wrinch's papers⁴.

In analysing the insulin structure on the basis of the X-ray evidence, there are two possible courses of procedure; that of discovering the maximum information that can be deduced from the position and relative intensity of the peaks on the Patterson diagram; and that of building an *a priori* model structure and attempting with it to account for the observed pattern. The first method, which I have described in a recent discussion on protein structure and which will be published in detail elsewhere, leads to a family of solutions obtainable by attributing different weights to the seven symmetrically distinct points in a hexagonal packing of two layers. A large number of these give no worse fits than the particular case which Dr. Wrinch claims as the unique solution. None of them, however, gives a complete fit, and to discriminate between them would appear, for lack of further experimental evidence, to present considerable difficulties.

The second method is one often employed in crystal analysis, but until now only for relatively simple structures. Its likelihood of success depends very largely on the possibility of selecting on the basis of chemical knowledge a structure which has a finite probability of being near to the true one. In the case of the protein this task is one of enormous difficulty, but Dr. Wrinch claims to have accomplished it with her cyclol cage model. In judging its *a priori* plausibility, two features need to be borne in mind; first, that it involves the assumption of a four-linked instead of a two-linked amino acid residue, for which no chemical evidence has been put forward and which, as Prof. Bergman⁵ and Dr. Neuburger⁶ have pointed out, is open to grave objections on chemical grounds; secondly, that it is only one arrangement, though admittedly a simple and symmetrical one, out of the multiple possibilities of arrangements of such four-linked residues. Nevertheless, if the proposed structure were found to account for the X-ray data, Dr. Wrinch would have a *prima facie* case for its acceptance.

To what extent, however, does it account for the X-ray data? Vector maps of Dr. Wrinch's hypothetical cyclol structure bear no resemblance to those which have been derived by Miss Crowfoot from her observations⁷. The distribution of atoms in the cyclol skeleton is far too continuous to give rise to any definite peaks, and no distribution of side chains can do other than increase the blurring of the picture. Dr. Wrinch has not however used the vector map of

the cyclol skeleton. Instead of this, she has chosen certain density concentrations, which are treated as positive and negative point scattering centres, for the construction of the vector diagrams. It is difficult to see on what principle in relation to the structure these centres have been chosen. Two of the strongest of them are completely arbitrary and another is attributed to a zinc atom the 28 electrons of which would scarcely seem effective scattering centres in a molecule with 20,000 electrons.

Even if the selected points led to the observed Patterson diagram, this would not prove the correctness of the cyclol structure, as the characteristic pattern is not involved in deriving them. At the most it would show that the cyclol model had been a useful working hypothesis for arriving at a structure based on scattering centres which might have very different physical structure. It is, however, certain that it does not do so. Out of the possible 3,600 vectors between scattering centres which this model would provide for the vector map, only thirteen are published in Dr. Winch's paper, but the selection is almost completely arbitrary as it contains vectors corresponding to weak pairs of scattering centres while many corresponding to strong pairs are omitted. It is stated that this omission makes no difference to the general agreement with the observed vector maps; but this is demonstrably incorrect, for a basal projection using *all* the vectors from the stronger scattering centres shows a pattern in which all resemblance with the observed vector map has vanished.

*In view of this, it can fairly be claimed that the scattering centre model derived from the cyclol hypothesis fails completely to account for the X-ray evidence for insulin, and further that the cyclol model itself leads to results incompatible with that evidence. In rejecting it, therefore, it is not necessary, however desirable, to put forward another model—the problem still remains an open one. Such a result is disappointing, but the discussion to which this attempt has given rise will not be wasted if it focuses attention on the need for an active collaboration of physicists and chemists in a concentrated attack on the structure of the protein molecule.

Vector Maps and Heavy Atoms in Crystal Analysis and the Insulin Structure

CONSIDERABLE discussion has recently been devoted to the use of vector maps in crystal analysis¹ based on the Patterson method². Although much use has been made of this method in the insulin structure³, the complexity of the problem and the inadequacy of the existing X-ray data to yield a solution in terms of atomic positions do not appear to have been sufficiently emphasized. It is quite obvious that fifty-nine relative measurements of amplitude cannot

define a structure consisting of several thousand atoms. So far as these measurements go, the structure is effectively a continuous distribution of scattering matter, and every arbitrary assignment of phase constants to the amplitudes will yield a solution. As individual atoms cannot appear in any of these solutions, there does not seem to be any rigid criterion in favour of one any more than another. The Patterson maps, which summarize the X-ray measurements, do not remove this ambiguity because, for a similar reason, we do not know what meaning to attach to the peaks in these maps. The suggestion that certain concentrations of atoms in the molecule can be treated as point scattering sources does not seem to constitute even a reasonable approximation. As no large gaps between the atoms are likely, it may also be very difficult to distinguish between regions of high and low density which are due to real features in the structure, and those which are due to unavoidable deficiencies in the series representing it.

The situation must be sharply contrasted with that of the more simple organic molecules, containing up to about forty atoms, which have been successfully analysed by the X-ray method. In these, the number of observed amplitudes is always very much greater than the number of co-ordinates defining the positions of the atoms, and an exact solution becomes feasible. It is accepted if it outlines the number of separate atoms required by chemical analysis, and if each of these atoms shows its expected scattering power for X-rays.

Even in these relatively simple organic structures (20–40 atoms), the Patterson method has not so far proved very helpful, in spite of its great power and usefulness where only a few atoms are concerned⁴. This is partly due to the difficulty of analysing structures where all the atoms (except hydrogen) have nearly the same scattering power for X-rays. A vast number of inter-atomic vectors results, all nearly equally important, while those which are prominent are frequently due to chance concurrences.

For many organic structures, a more powerful method of attack is available, and has recently been extensively developed and studied^{5,6}. By chemical methods a heavy atom can often be inserted in an organic molecule the structure of which has to be determined. Co-ordinated complexes with metal atoms are sometimes easy to make, and with unsaturated compounds, alcohols, acids and certain weak bases, it is in general possible to insert a heavy halogen.

Stated very briefly, the effect of an atom of high scattering power in a complex structure is to translate the unknown phase differences of the X-ray reflections into differences of amplitude which can be measured. In terms of the Patterson method, the vectors between the light atoms become unimportant, and we obtain only the vectors connecting the heavy atom to each of the light atoms—in other words, we get the actual structure directly, instead of its vector representation.

The method must be adjusted to particular cases. When several heavy atoms are involved, their relative positions may be deduced from a preliminary Patterson analysis. With an origin related to these atoms, a subsequent analysis employing the phase constants due to these atoms may then reveal the finer detail. In an isomorphous series, still better results may be obtained from the differential effect of substituting successively heavier atoms^{7,8}.

One very important point is that the swamping effect of a heavy atom on the contributions from the

lighter atoms does not depend very much on the size of the molecule, or the number of these lighter atoms, provided that (as is generally the case for organic molecular structures) there is no definite integral relationship between such intra-molecular periodicities as may exist and the cell dimensions of the crystal. As the molecule gets larger, the geometrical structure factors on the average depart further from their possible maxima. The contributions from the various atoms tend to cancel each other out, and we are left with a small residual. This is, in fact, one of the essential difficulties in analysing a complex structure by trial. A comparatively small change in the structure may mean a big change in these small residuals. But the contribution from the heavy atom is constant and will continue to dominate the situation. In a recent example⁶, a nickel atom, representing only about 10 per cent of the total molecular weight, was found to determine practically all the phase constants.

It may be going too far to suggest that the insulin structure could be determined in this way. The molecule does, however, contain a few zinc atoms, and if these could be replaced by mercury, as has been suggested, a very profitable study might ensue. Of course there are formidable difficulties. If the reflections are swamped in the manner described, much greater accuracy is required in the intensity determinations to reveal the small differences. In the same way, a higher numerical accuracy is required in the calculations to reveal the minor maxima and differentiate them from spurious effects. Recent results have shown that these difficulties can be overcome in a moderately complex molecular structure⁷.

A Temperature Effect in Laue Photographs

DURING a study of age-hardening in single crystals of aluminium containing 4 per cent copper, certain anomalies in the Laue photographs were noticed¹.

Aluminium at 20° C.

Aluminium at 550° C.

Some of these were associated with the progress of hardening, but others appeared to be due to another cause. Further investigation showed the presence on the Laue photographs of single crystals of aluminium, of certain faint streaks also observed in photographs of the alloy. When photographed at 550° C., the intensity of these streaks or ill-defined spots greatly increased. Similar effects were observed in sodium chloride and magnesium oxide. The effect observed in sodium chloride at room temperature has already been noted by Wadlund², and an explanation of its origin given by Zachariasen³. The fact that the effect becomes much more intense when the temperature is raised suggests that it is due to thermal vibrations of the lattice. In diamond at 500° C. a faint effect similar to that obtained with the other crystals is present, although little is to be seen at room temperature.

The photographs reproduced herewith illustrate the effect in aluminium. The X-ray beam is parallel to (001) and (110) is vertical; they were taken with a silver target with 60 kv. peak on the tube. The intense spots near the centre are largely due to the silver characteristic radiation, and have also been recorded with monochromatic radiation yielding a 'cross grating' pattern in which the spots have indexes (20) and (81).

Flavo-Protein of the Heart Muscle Tissue

I HAVE shown previously¹ that the coenzyme of the *D*-amino-acid oxidase is present not only in liver and kidney tissues, which exhibit the *D*-amino acid oxidase activity, but also in skeletal and heart muscles devoid of this enzyme. If washed muscle tissue is added to the alanine test (coenzyme-free *D*-amino acid oxidase and alanine), no oxygen uptake is detected. If, however, the extract of a boiled washed muscle suspension is added to the test, vigorous oxygen uptake takes place. It is clear that the coenzyme of the *D*-amino acid oxidase, a flavin compound, is present in a bound form, probably as the prosthetic group of a hitherto unknown enzyme.

When cytochrome oxidase is prepared according to the method of Keilin and Hartree², it is found that the flavin nucleotide follows the cytochrome oxidase and the group of insoluble dehydrogenases. I have now found that a flavo-protein can be extracted from such muscle preparations by the action of dilute alcohol and salt solution. Following this extraction, the flavo-protein has been gradually purified to a flavin phosphate content of 0.65 per cent. This new flavo-protein can be regarded as practically pure,

considering that 0.7 per cent of flavin phosphate found by Haas² in his flavo-protein from yeast is the highest flavin content so far obtained.

The new flavo-protein is readily soluble in distilled water, giving a greenish yellow solution. The prosthetic group can replace quantitatively the coenzyme of the *D*-amino-acid oxidase and is considered to be the same compound.

The details of the purification will be given elsewhere.

Sulphanilamides and Rabies

HITHERTO, chemotherapy has seldom been successful in virus diseases, but the use of sulphanilamides in lymphogranuloma inguinale¹, choriomeningitis², and trachoma³ has opened new possibilities in this field during the past year. There is, so far, no record of experimental work giving favourable results in the chemotherapy of rabies, however, and from an observation in Khartoum, the sulphanilamides appear to have no effect in this condition.

Four rabbits, of approximately equal size and weight, were infected subdurally with an emulsion of fixed virus (Paris strain), and three of these were given 1 c.c. Promotil Soluble daily by the intravenous route for the following six days. The fourth was kept as a control, although this virus has never failed in Khartoum to produce paralytic rabies in six to seven days during numerous passages through sheep and rabbits since 1935, when it was obtained from the Public Health Laboratories in Jerusalem. By the seventh day all four rabbits were moribund, with typical signs of paralytic rabies, and were killed. No difference could be observed between the treated animals and the control, either in the incubation period or in any other feature of the disease.

Immunity to Experimental Pneumococcus Infection with an Artificial Antigen

FOR the past few years, we have been engaged in this laboratory in studying the factors which govern the immunological specificity of carbohydrates. This problem has been approached by an investigation of the chemical structure of the specific bacterial polysaccharides themselves and by a study of the immunological properties of artificial antigens prepared by combining the aminophenol or benzyl glycosides of saccharides of known structure with protein. The latter method has been of particular value in revealing certain of the fundamental factors which govern the specificity of carbohydrates. The stereochemical configuration of simple hexoses¹, the

configuration of intramolecular linkages of disaccharides and the position of such linkages² are all important determinants in orienting the specificities of these saccharides. More recently it has been found that the conversion of the primary alcohol group of a hexose to the carboxyl group likewise alters the immunological properties of artificial antigens containing the hexoses, as opposed to those containing the hexose uronic acids³.

Although antigens containing the hexose-uronic acids possess certain of the serological characteristics of the specific pneumococcus polysaccharides, for they precipitate in high dilutions in anti-pneumococcal horse sera of various types, it has as yet not been possible to produce anti-pneumococcal immunity by injecting animals with the glucuronic and galacturonic acid antigens. The reason probably is due to the fact that the hexose uronic acids do not approximate closely enough in structure to the more complex building stones of certain of the pneumococcus polysaccharides, the aldobionic acids. These observations have led to the belief that in order to evoke anti-pneumococcal immunity in experimental animals with an artificial antigen, it is not necessary to have as the immuno-specific group a long-chained type specific polysaccharide, but that a simpler saccharide, the pattern unit from which the polysaccharide is constituted, should suffice.

An artificial antigen has therefore been prepared by combining the diazonium derivative of the *p*-amino benzyl glycoside of cellobiuronic acid, the aldobionic acid from which the Type III pneumococcus polysaccharide is constituted⁴, with horse serum globulin⁵. For purposes of comparison, a similar antigen containing the corresponding glycoside of cellobiose has also been prepared. The chemical structure of the cellobioside and cellobiuronide is identical save for the grouping occupying the 12th position, as can be seen from the accompanying graphic formulae.

p-aminobenzyl β -cellobioside

p-aminobenzyl β -cellobiuronide

This difference in chemical structure suffices, however, to confer on each antigen containing the glycosides vastly different immunological properties. The sera of rabbits injected with the cellobiuronic antigen precipitate the Type III pneumococcus specific polysaccharide, agglutinate Type III pneumococci, and produce a typical swelling of the capsule when living Type III organisms are mixed with the anti-serum.

Furthermore, the cellobiuronic acid antisera confer passive protection on mice against infection with virulent Types II, III and VIII pneumococci. The animals injected with the artificial cellobiuronic acid antigen acquire active resistance to infection with virulent Type III pneumococci as well. The sera of rabbits injected with the cellobiose antigen, on the other hand, exhibit none of these phenomena, nor are the rabbits themselves resistant to Type III pneumococcal infections.

These experiments demonstrate that cellobiuronic acid has an important immunochemical function in determining the immunological properties of Types II, III and VIII pneumococci. It is apparent, furthermore, that antibacterial immunity can be evoked by injecting experimental animals with an artificial antigen containing as the immuno specific group the pattern unit of the polysaccharide rather than the intact carbohydrate itself. The results of these experimental studies have brought forth still a new and important principle. Whereas an antigen containing the complex bacterial carbohydrate of Type III pneumococcus gives rise to antibodies which are type specific, those elicited by the antigen containing the pattern unit, or aldobionic acid, exhibit broader specificity and afford passive protection in mice against infection with Types II and VIII pneumococci as well.

In 1936, I described at the Second International Congress for Microbiology in London the synthesis of two aldobionic acids, asciabiuronic and gentiobiuronic acids¹. Whether these synthetic saccharides, when combined with protein, will evoke antibacterial immunity in experimental animals is a problem under investigation at the present time.

Chromosomes of *Cimex*

THE conclusions drawn from the numbers of chromosomes found during spermatogenesis in *Cimex spp.*¹ require considerable modification as a result of the examination of further material. New evidence of the nature of the variable elements and of their numerical range has given a different aspect to the problem.

In three wild populations of *C. lectularius*, including the type previously considered to be a sub-species², 13 autosome pairs are constantly present and behave normally, also observed by Darlington³. They divide reductionally at the first meiotic division and equationally at the second, forming an equatorial ring at metaphase. Within this ring lies a group of elements which have divided equationally at the

first division. Variation in chromosome number is due to variation within this group. A continuous series of modal values from 8 to 16 has been found in different individuals, with a maximum deviation from the mode of ± 3 in any one individual.

This central group contains the sex chromosomes, one of which, distinguished by its shape, staining capacity and position, is present in every second metaphase complement. From the frequent secondary pairing of this chromosome with two others of the central group, I am of the opinion that the male *C. lectularius* has an XXY sex mechanism. Comparison with the karyo-type of *C. rotundatus* supports this view, for in this species all the nuclei which have been examined invariably showed 14 pairs of autosomes and three sex chromosomes, with no other central elements.

SECOND METAPHASE FIGURES OF (a) *C. lectularius*,
(b) *C. rotundatus*.

In *C. lectularius* the variations in chromosome number that have been observed seem to be due to unequal division at first anaphase and unequal segregation at second anaphase of a group of inert chromosomes, possibly related to the sex chromosomes. The first division results in variation of chromosome complements in the same individual, the second division produces variations between individuals. From counts of two nuclei there is evidence that the female possesses a similar chromosome constitution. These phenomena I intend to analyse in greater detail in a future publication.

Irritant Exudation from a Centipede

MR. E. BURT's experience¹ with the East African millipede *Spirobolus* reminds me of an incident with the Melanesian centipede, *Scolopendra*, in the Solomon Islands.

An individual about seven inches in length was picked up with a pair of entomological forceps, care being taken to see that none of the poison from the large mandibles reached the skin. Some of the twenty or so pairs of legs did touch my hand, as a consequence of which the back of the hand had a painful numbness for the rest of that evening and during the same night. Although this irritation was clearly not comparable in intensity with that caused by the

repugnatorial glands of the millipede, it seems worth recording, as F. G. Sinclair¹ refers only to the mandibular poison in the Chilopoda, which would seem to have, at least in the genus *Scolopendra*, a strong irritant in the paired appendages.

• Soil Erosion in England

DURING the past few years, the possibilities of soil erosion in Great Britain have been in question owing to the immense loss of good farmland in large areas of the United States, Canada, and many tropical countries as the result of the exhaustive systems of farming carried on during past years. The very heavy rainfall of exceptional intensity on two days this autumn in Devon has enabled us to obtain some idea of the possible intensity of soil erosion under the systems of cultivation of south-west England.

On August 4, 3.90 in. of rain were recorded at Totnes between 2.30 a.m. and 9 a.m. G.M.T., and on November 26, 1.24 in. were recorded between 6.15 p.m. and 7.35 p.m. G.M.T. and a further 1.67 in. between 11 p.m. (26) and 9 a.m. (27) G.M.T. The exact duration of the second storm is not known, although it probably lasted only about 1½ hours. Robinson¹ states that the rate of erosion of soil by running water depends principally on four factors, namely: (1) the amount and intensity of the rainfall; (2) the angle of slope; (3) the presence or absence of a vegetative cover, and, if present, its character; and (4) the nature of the soil itself. Under the conditions experienced in Devon, sheet erosion alone took place on most slopes up to about 1 in 10, while no gully erosion was found on slopes of less than about 1 in 6. The amount of possible erosion was restricted owing to the high proportion of grassland in this part of the country. Very good protection was also given by thick and high cover crops, such as wheat, oats and marrow-stem kale. Even a thin covering of weeds afforded quite good protection from erosion; but root crops gave little or none, and even appeared in some places to encourage gullying.

Severe gullying occurred on farms on the fringe of Dartmoor, while the most marked instances of soil erosion off the Moor were found on the red conglomerate soils derived from Permian breccia in the Paignton district and on a dark soil derived from Middle Devonian shales and tuffs.

The work of Bennett in the United States² tends to show that soils the clay fractions of which have high $\text{SiO}_2/\text{R}_2\text{O}_3$ ratios are erosive, and that there is a critical ratio at 2. The $\text{SiO}_2/\text{R}_2\text{O}_3$ ratios of the clay fractions of the surface horizons of the two Devon soils mentioned are 1.98 and 1.90 respectively. The average ratio for most of the cultivated surface soils in Devon is about 1.6, which tends to show that most of them have been eroded in past times and have now settled down under cultivation to a comparatively stable condition, as have those of North Wales, where the climate is very similar to that in south Devon. The recent observations, however, seem to show that this state is due largely to the

type of agriculture practised in the region, and that a return to predominantly arable conditions in the hilly country might result in the impoverishment of soils by erosion.

A School of Whale Sharks in the Bahama Islands

FOR years I have received newspaper clippings and second-hand verbal recitals of whale sharks seen off the west side of the Bahamas. Much effort was made to verify these, but for a long time I had no evidence of scientific value. However, in July 1938, there came to me authentic data concerning a specimen seen off Bimini, and shortly thereafter I published a faunal record for *Rhinochondrion* in the Bahamas¹.

In my studies of the distribution of the whale shark, I have long had the aid of the U.S. Hydrographic Office. It has asked ships' officers for reports of their observations all over the world of this great shark. These reports can be very definitely made because of the great size of the shark, its broad head and terminal mouth, and the chequer-board arrangement of bars and spots on the sides makes its identification easy. The latest report to the Hydrographic Office was from Mr. E. R. Fenimore Johnson of Camden, New Jersey, U.S.A.

On June 3, 1938, Mr. Johnson, in his ketch *Elsie Fenimore*, ran into a school of about twelve whale sharks in lat. $24^{\circ} 32' \text{ N.}$ and long. $77^{\circ} 37' \text{ W.}$, about four miles east of Sugar Cay, in the "Tongue of the Ocean". The school was under observation for nearly an hour and, the sea being fairly smooth and the sharks close to the boat, Mr. Johnson made careful notes of the behaviour of the fish and took some 200 ft. of moving-picture film of various individuals as they swam around the vessel.

Being without fear, these sharks swam so close to the boat that "We could easily have jumped astride their backs"—an observation which parallels Dr. William Beebe's off Cape San Lucas, Lower California. Mr. Johnson adds, "We ran into one fish, but he did not seem greatly upset, and his efforts to get clear were quite sluggish". This also is what has been reported by many others. The fish has no enemies, and is not afraid of a man or a boat.

The school was made up of a dozen individuals ranging in length from about 18 ft. to about 31 ft. The school had no formation, but was spread out irregularly over an area of about a quarter of a mile square. The fish did not seem to be going anywhere, and an individual shark would swim over a small area and would turn and go over it again as if hunting for something. Mr. Johnson courteously loaned me the film showing this behaviour. Close study of it convinced me that the fish were feeding by swimming about with their wide terminal mouths partly open. When asked about this, Mr. Johnson gave me definite information.

These were engaged in feeding. A fish would swim for an interval of one or two minutes with its mouth open and with its upper jaw about even with the

surface of the water. It always had its dorsal fin and the upper lobe of its tail fin well out of water. Then the fish would dive to a shallow depth for a short interval and would come to the surface and repeat the manoeuvre. The water was examined by naked eye, but was found to contain only scattered jelly fish about 15 mm. in diameter.

I have long conjectured that *Rhincodon* feeds by swimming at the surface of the water with open mouth, that small organisms are strained out by the sieve-like gill structures and that the water passes out through the gill-openings. Mr. Johnson is fortunate in being the first observer to witness this manner of feeding and to photograph the fish in the act.

Sound Absorption of Snow

THE impressive and all-pervading quietness following a fall of snow is a commonplace experience, though, so far as we are aware, no measurements of the sound absorption of snow have been published. The recent cold spell provided a suitable opportunity to make such measurements in the reverberation chamber of the National Physical Laboratory.

Two specimens of freshly fallen snow were tested, each measuring 10 feet square, one approximately 1 inch thick, the other approximately 4 inches thick. The measurements were necessarily conducted somewhat hurriedly, and the results which are given in the accompanying table for various frequencies from 125 to 4000 cycles per second (that is, virtually the speech range), can only be approximate.

Thickness of snow	Absorption coefficients for the following frequencies:					
	125	50	500	1000	2000	4000
1 inch	0.15	0.40	0.65	0.75	0.80	0.85
4 "	0.45	0.75	0.90	0.95	0.95	0.95

It will be seen that freshly fallen snow is highly absorbent, its effectiveness being equalled by few known materials of corresponding thickness. In particular, a 4-inch layer absorbs as much as 90 per cent or more of the intensity of medium and high-pitched notes; and greater thicknesses would no doubt present equally striking figures for low-pitched notes. Thus, apart from the muting of impact noises, the 'deadening' effect of a layer of snow can be well understood.

E. J. EVANS.

Points from Foregoing Letters

PROF. W. L. BRAGG discusses the recent communications by Dr. D. Wrinch and Prof. E. H. Neville in which it is claimed that a new method of interpreting the Patterson X-ray diagrams enables the identification of the structure of the insulin molecule. He points out that the method suggested is essentially the same as that previously used by several investigators, but the assumption that the insulin diagram can be explained by a certain concentration of scattering matter in a simple way at a few typical points in the molecule, appears risky.

Writing on the same subject, Prof. J. D. Bernal criticises the suggestion of Prof. Neville that points may be substituted for peaks in the Patterson vector map. He claims that the scattering centre model derived from the cyclol hypothesis fails completely to account for the X-ray evidence for insulin and that the cyclol model itself leads to results incompatible with that evidence.

Finally, Dr. J. M. Robertson considers that fifty-nine relative measurements of amplitude cannot define a structure consisting of several thousand atoms; he suggests that by the introduction of heavier mercury atoms in place of the zinc atoms present in the insulin molecule it may be possible to obtain diagrams that would throw some light on the structure of the molecule.

Photographs of Laue X-ray diffraction patterns obtained with aluminium at 20° and 550° C. are submitted by G. D. Preston. Certain spots and streaks which are only faintly marked at 20°, become considerably intensified at 550°, and the author considers that the effect is to be attributed to the thermal agitation of the crystal lattice.

A flavo-protein extracted from the heart muscle tissue with dilute alcohol and salt solution is found by Dr. F. B. Straub to contain 0.65 per cent of flavin phosphate. Its non-protein group can replace quantitatively the co-enzyme of the δ -amino-acid oxidase and is probably the same compound.

An artificial antigen which, when injected into rabbits, yields sera that agglutinate Type III pneumococci, has been prepared by Dr. W. F. Goebel by combining the diazonium derivative of the *p*-amino benzyl glucoside of cellobiuronic acid with horse serum globulin. The cellobiuronic acid antisera confer passive protection on mice against virulent Types II, III and VIII pneumococci.

New evidence of numerical variation in the chromosomes of *Oimex* spp. and of the nature of the variable elements has led Dr. H. D. Slack to modify his former concept of the polyploid origin of the genus, since the different numbers form a continuous series derived from the irregular distribution of a specialized group of chromosomes.

R. A. Lever writes that contact with some of the legs of the melanesian centipede, *Scolopendra*, produced numbness of the back of the hand, so it appears that the irritant exudation already referred to by Mr. Burt is not confined to the mandibles.

Observations following upon two heavy rainfalls, in August and November, in Devon, show, according to J. B. E. Patterson, that gully erosion takes place on slopes greater than 1 in 6 and that sheet erosion occurs on most slopes up to 1 in 10. Weeds afford quite good protection from erosion but root crops appear to give little or none.

Research Items

Stone Age Culture from Kenya Colony

A STONE age culture, for which the name 'Kombewa culture' is suggested from the name of the locality in which it occurs, is described by the Venerable Archdeacon W. E. Owen in *Man* of December 1938. Kombewa is the name of a subsection of the Location of Senle in the Central Kavirondo District of the Nyanza Province, Kenya Colony. It lies about half-way up the escarpment on the north of the Kavirondo Gulf and about eight miles from it. Between 1932 and 1938, four workshop sites were discovered, and single specimens have been found over a wide area. Three sites were hill-top sites and showed no stratification, but stratified rubbles, carrying both rolled and unrolled hand-axes of Acheulean type, flakes and cores, were found at Aringo and Ng'ira in Karungu on the east coast of Lake Victoria, and subsequent search revealed the fourth workshop site on the slopes of Nyandwat Hill, near Ng'ira. The raw material in every instance is the local rock, large, medium or small flakes being struck from a selected block. In the majority of instances care had been taken to prepare the area from which the butt of the flake tool was removed, so that many tools show a faceted or trimmed butt. The peculiarity of the tool is its perfectly plain upper surface. The struck cores are classified under four heads with reference to the butt area into natural butts, faceted butts with central ridge, faceted butts with trimmed ridge, and rounded butts. The majority of cores show only one tool removed. Finished tools are small in number compared with cores. The outline is approximately rectangular with rounded corners, ovate and nearly round to semicircular. The butts are generally as wide as the widest part of the flake. Some of the cores seem to have been used as scrapers. One large flake seems to have been a chopper, and two hammer stones were found. The suggested date is Middle Stone Age; but at the present stage it suffices to remember that at Ng'ira specimens occur in a horizon carrying rolled and unrolled Acheulean tools.

Formation of Pronephric Duct

Two views have been put forward regarding the method of formation of the pronephric duct in the urodele Amphibia. First, that it is produced by a backward growth from the pronephric rudiment, and secondly that it is a composite structure resulting from the fusion of a series of segmental units. By means of *intra vitam* staining with Nile blue sulphate and by means of operative interference, R. J. O'Connor has thrown light on this problem (*J. Anat.*, Oct. 1938). The types chosen were *Ambystoma tigrinum* and *Triton cristatus*. It was shown that when the caudal end of the rudiment of the duct is stained and then development allowed to proceed, the stain is carried on by the growing rudiment right down to the cloaca in the walls of the duct when formed. Also that if a piece of some other tissue is interposed caudal to the end of the rudiment, it prevents the backward extension of the rudiment and so prevents the formation of a pronephric duct. From this, it is concluded that the duct is developed from a backward extension of the pronephric rudiment.

New Type of Hereditary Behaviour in Fishes

Mollienisia is a genus of cyprinodont fishes. *M. sphenops* occurs around the Gulf of Mexico from Florida to northern Mexico. *M. latipinna* is found in southern Mexico and Central America. Where these species overlap is found an intermediate form known as *M. formosa*, which is evidently of hybrid origin but occurs exclusively as females. This peculiar situation has been investigated by Mr. Henry Meyer (*J. Genetics*, 36, No. 3). When *M. formosa* is mated to either species, the offspring are all females of maternal type. But this is not parthenogenesis, since unmated females produce no young. The two species and the laboratory hybrid between them all had 36 chromosomes, and nuclear size suggests that the *M. formosa* females are also diploid. There was no differential death-rate either before or after the birth of the young which would account for the absence of males. There is no tendency to hermaphroditism, and sex reversal is improbable. To account for the purely matroclinal inheritance, the following explanation is suggested. The eggs of *M. formosa* are fertilized by the other two species, but the paternal chromosomes remain inactive in the foreign cytoplasm. In maturation of the eggs of the hybrids, the paternal chromosomes are all eliminated into the polar body. This condition is compared with meiosis in *Oenothera* hybrids and in the homopteran *Pseudococcus nipae*. Further cytological investigation should settle whether this explanation is correct.

Double-grafted Apple Trees

THE ancient problem of the reciprocal influence of scion and stock is further complicated by the increasing use in various parts of the world of fruit trees with two or more graft unions and composed of more than two varieties. Trees are frequently built up *ab initio* with a third variety used as an intermediate stem piece between stock and scion, whilst it is a common practice with established trees to graft shoots of a new variety on to the framework branches of an existing scion. M. O. Vyvyan (*J. Pom. and Hort. Sci.*, 16, 251; 1938) has investigated the effect on a given scion of stock varieties used both as rootstock and intermediate stem piece. The scion was always Stirling Castle, the stocks and intermediate pieces being *M* IX and *M* XII combined in all four possible ways, namely, XII/XII, IX/XII, XII/IX and IX/IX. The trees of type XII/XII were largest and those of type IX/IX the smallest. IX/XII trees, that is IX as intermediate and XII as rootstock, were intermediate in size, whilst XII/IX trees were only slightly larger than IX/IX trees. Trees with vigorous (XII) root systems or intermediate pieces produced more wood growth and fewer fruit buds per metre of wood than those with dwarfing (IX) root systems or intermediates, and in this respect the root system tended to have a greater influence than the intermediate piece. Swellings at some of the graft unions indicated that obstruction at the union may be in part responsible for some of the effects observed, but it is noted that an unworked *M* IX tree becomes dwarfed and precocious though no graft union is present.

Theory of Coacervation

AN interesting paper by Dr. Irving Langmuir (*J. Chem. Phys.*, 6, 873; 1938) deals with a new theory of coacervation. Unipolar coacervation results from micelles of similar charge, and bipolar coacervation from micelles of unlike charge. The formation of tactoids from thixotropic sols, of Schiller layers from ferric oxide sols, the separation of tobacco virus solutions and bentonite sols into two liquid layers, and the crystallization of proteins are regarded as being typical of unipolar coacervation, and involve attractive forces. The previous ideas about Coulombic attraction are shown to give an excessive attractive force between micelles and oppositely charged ions which must be compensated by repulsive forces and by the dispersive action of thermal agitation. Long-range van der Waals forces are discarded and a new theory of coacervation, based on the Debye-Hückel theory of the osmotic pressure of electrolytes, is developed mathematically. The limitations of the Debye-Hückel theory are discussed. A theory of relaxation of birefringence has also been worked out in which dilute thixotropic sols of bentonite are assumed to be arranged normally in a cubic lattice, and temporary shear in the liquid orients the micelles and produces birefringence although the lattice remains cubic. In bipolar coacervation, the electric fields and the charges on the micelles increase as the molecular concentration increases until at a certain concentration the field attains a value so high as to cause increased hydration which keeps the micelles apart and confers stability to the coacervate.

Wind Speed by Kites

THE considerable altitudes to which Japanese humming kites can ascend without their notes becoming inaudible on the ground seemed to provide a convenient method of determining the speed of the wind at these altitudes, and S. Suzuki and Z. Miduno of the University of Hukuoka have investigated the effects of wind speed on the pitch and amplitude of the stretched ribbon which hums (*Proc. Physico-Math. Soc. Japan*, Nov. 1938). The ribbon used was of metal about 80 cm. long, 0.3 cm. broad and 0.011 cm. thick stretched horizontally in a wind tunnel and its motion determined by light reflected from a small mirror. The wind stream was parallel to the breadth of the ribbon. The oscillations are principally torsional and their fundamental frequency is that of the transverse oscillation, a thin round wire of the same length and mass per unit length under a stretching force exceeding that used by $16\pi^2 b^2/a$, where n is the rigidity of the material of the ribbon, a half the breadth and b half the thickness. The speed of the wind has very little effect on the pitch of the fundamental note but a considerable effect on the amplitude and on those of the harmonics, and it is these effects which the authors hope to use as means of measuring the wind speed.

Corpuscular Eclipse of October 1, 1940

A RECENT paper (*Mon. Not. Roy. Astro. Soc.*, 98, 9, Supplementary Number, Oct. 1938) gives a description of the application of the occultation machine in the Nautical Almanac Office to the prediction of the corpuscular eclipse. The velocity of the corpuscles emitted from the sun is about 1,000 miles a second and large 'aberration' terms are necessarily introduced into the positions of the sun and moon, the values corresponding to corrections representing

'light-times' of 1.0706 days and 221 seconds for the sun and moon respectively. There is some doubt regarding the manner in which the corpuscles leave the sun. If they are expelled radially it is obvious that the sun must be treated as a point-source, but this assumption does not accord with observation. There are no reliable data, however, to show the most suitable diameter to adopt, though it is certain that it must be considerably less than that of the visual sun, and about the order of one fourth of its apparent diameter. A table supplies the corrected times of beginning and end of the corpuscular eclipse at all points in the network covering South Africa. A map shows the track of the corpuscular eclipse for a height of 300 km.—the height of the upper ionized layer of the atmosphere, from which wireless waves are reflected. There is very little difference in the times of beginning and ending between the 300 km. height and the 100 km. height at which the lower ionized layer exists, except, as might be expected, near the end and edges of the track. In addition to the assumed speed of 1,000 miles a second, Bosscher elements have been computed and predictions made for a speed of 1,100 miles a second. The general effect of this increased speed of propagation is to displace the track towards the south and west and the times are later by 10–16 minutes. It is hoped that much useful information will be derived from this corpuscular eclipse. The paper is communicated by the Astronomer Royal.

Polar Aurora and Night-Sky Light

PROF. H. H. PLASKETT has recently published a paper with the above title (*Occas. Notes, Roy. Astro. Soc.*, No. 2, Oct. 1938), in which he gives a summary of the methods for studying these two phenomena. It may be mentioned that the object of these *Occasional Notes* is to provide a fairly simple and non-technical description of various astronomical matters which can be followed by the general astronomical reader, and for this reason many non-astronomers will find the paper very interesting. Dufay's night-sky photometer, described very briefly in the paper, has been found the most satisfactory for the study of the night-sky light, and Brunner has accomplished some valuable work by means of this apparatus. He has found that the increase of surface brightness with zenith distance to a maximum at 70° can be represented if two main sources are postulated—a low-lying layer at a height of 5 km. which contributes more than half the surface brightness, and upper layers at heights of 1,000 km. or more, the contribution of the latter being variable with time: on the average it is the equivalent of one first magnitude star every 66 square degrees. Brunner attributes the low-lying component to diffuse reflection by the lower atmosphere of light already reflected off the surface of the earth. The origin of the upper component and also of the aurora is discussed and a brief reference is made to the various theories which have proved acceptable for a time but which are open to serious objections. Hulburt and Maris have recently abandoned the solar-stream hypothesis, and they believe that the charged particles responsible for the aurora are produced in the earth's atmosphere from ionization by the ultra-violet light of the sun. The theory has not, however, been generally accepted, and more research is necessary before it is possible to make any definite pronouncement on the causes of the night-sky light and of the aurora.

Discriminatory Effect of Ultra-violet Rays on Mutation in *Drosophila*

By Dr. H. J. Muller and Dr. K. Mackenzie,

Institute of Animal Genetics, University of Edinburgh

THE discovery that rearrangements of genes in *Drosophila* produce 'position effects' like the effects of 'gene mutations', and that such rearrangements may be so minute as to be practically indistinguishable cytologically or genetically from gene mutations¹ has raised the question whether there is any essential distinction between so-called gene rearrangements and gene mutations, or whether the latter are to be regarded merely as special cases, at the extreme lower limit of size, of the former. This question, fundamental both to problems of genetics and of the biological action of radiation, has recently become more acute since it has become known that, although gross rearrangements vary in frequency as the $3/2$ power of the number of ions produced by X-ray irradiation^{2,3,4} (indicating that they commonly involve the reunion of chromosomes broken at two or more separated points by separate ionizations or activations), minute rearrangements, like 'gene mutations', vary directly as the number of the ions^{4,5} (indicating that two breaks near together may result from one ionization or activation).

If, now, an agent could be found which discriminated between either gross or minute rearrangements and 'gene mutations', producing the latter but not the former (even when used in sufficient strength and in such circumstances as to have allowed an appreciable number of the gross rearrangements to be formed according to the $3/2$ exponential rule, provided the points of genetic change had really represented effective breakages), then there would be *prima facie* evidence that the breakages giving rise to these rearrangements were in some way different from the changes resulting in the gene mutations. After some earlier negative results it had been convincingly demonstrated by Altenburg⁶ (1930, 1931) and corroborated by Reuss⁷, who obtained more intense effects (the results of Geigy⁸ and of Promptoff⁹ in 1931 and 1932, concerning this question were rather inconclusive), that ultra-violet light produces gene mutations in *Drosophila*. Shortly after his first positive results on ultra-violet gene mutations, Altenburg (1931, 1936) made some rather extensive tests for gross rearrangements (both inversions and translocations) but did not obtain any⁶. These results were, however, admittedly insufficient for a decision, since part of the treatments were of cells (embryonic) in which the chromosome conformation is unfavourable to the reunion of widely separated breakage points, even when produced by X-rays, and since the rest involved treatments which, in the light of our exponential rule, we now know to have been of too low a strength as judged by the frequency of the gene mutations produced, to have allowed an appreciable production of gross rearrangements (in view of the latter's resulting from two independent ionizations or activations).

Not long after Altenburg's findings, it was proved by Noethling and Stubbe¹⁰ (1934) that ultra-violet light produces gene mutations in pollen of *Anthr-*

rhinum; Stadler and Sprague¹¹ soon afterwards (1936) obtained similar results with maize pollen. Stadler and Uber¹² then attacked the problem of the relative effectiveness of ultra-violet in producing gene mutations, gross rearrangements of the translocation type, and other changes in maize pollen. Using a sufficiently strong dose, as shown by the frequency of induced gene mutations, they succeeded in demonstrating that in this material the genetic effect of ultra-violet light is qualitatively different from that of X-rays in that the former produces gene mutations without translocations, or with a far lower frequency than the latter. It has remained necessary, however, to test this question on *Drosophila* also, not only because this organism, standing almost at the opposite pole of the organic world from the plant material, might, *a priori*, present fundamental differences, but also because the known differences in genetic reactions (especially the lack or dearth of 'position effect' in the plants and the apparent occurrence of single-break chromosome changes in them) indicated that the hereditary material might be differently constituted, in that, for example, as Brink¹³ had suggested, the genes in the plants might conceivably be grouped in batches having differing connexions between, from those within, the latter.

In the present experiments, adult male *Drosophila* were irradiated with ultra-violet light, since in the mature spermatozoa, with their crowded chromosomes, rearrangements are produced far more readily than in other cells. To allow maximal treatments, they were held immobile by the pressure of the quartz cover glass so as to allow irradiation through their ventral surface, according to Reuss's technique, with modifications, and young 'yellow-white' flies with the minimum of pigmentation were used. To reduce the 'burning' action and so to allow a greater dose of wave-lengths of 280–310 m μ , which both Stubbe and Noethling¹⁴, and Stadler and Uber¹² had found to be genetically very effective, a 2-mm. filter (either Schott and Gen. 'U.G.2', melt 4924, or Chance 'Uviol') cutting off wave-lengths shorter than 280 m μ and most of those longer than 400 m μ was used. The source was a water-cooled capillary mercury arc of the type of Daniels, Farrington and Heidt¹⁵, consuming about 500 watts. After the lethal dose had been determined by experimentation, a dose 50–80 per cent as strong as this was applied to the flies to be bred. Total ultra-violet dose applied was determined by a Weston photronic cell, standardized against oxalic acid-uranyl sulphate solution; it varied from 2.0×10^{10} to 4.0×10^{10} quanta with the U.G.2 filter to 3.0–5.5 for the Chance filter, this being given by 20 minutes' exposure at 7 cm. from the source. The lots of flies (of about forty each) were divided at random after treatment, about one third being tested for lethals (representing gene mutations) by the 'CIB' method, and the rest tested for translocation of all major chromosomes, by crosses to females with attached X's and the 'markers' yellow brown

ebony eyeless, followed by back-crosses of the F_1 males to flies of the same stock.

In a preliminary experiment (irradiation of March 15) 165 of the F_1 cultures tested for lethals yielded 4 lethals (2.4 per cent), while 125 tested for translocations yielded none. Irradiations of April 19-21 led to 213 cultures with 7 lethals (3.3 per cent) and 305 cultures, from flies irradiated with half this dose, with no translocations. The later irradiations have given a total of 1,070 CLB cultures with 22 lethals, or 2.1 per cent, and 2,449 cultures tested for translocations, with not one case of the latter. 579 control cultures (not treated) gave only one lethal, and infra-red rays, in semi-lethal dose, gave 1 lethal in 252 F_1 cultures. The latter results show that the great majority of the lethals in the treated series had resulted from the ultra-violet irradiation.

Our tests with X-rays⁸ have shown that the above represents a frequency of lethals such as is produced by about 600 r. and that with this dose there are some 0.8 per cent of translocations produced in spermatozoa (more exact tests are in progress). With the above numbers of F_1 cultures tested for translocations, then there would have been some 13 to 26 translocations in all, instead of none, had X-rays of the same gene-mutation-inducing dose been used. The difference between this and the result obtained (0) is statistically significant. Moreover, 28 of the ultra-violet lethals, tested for crossing over, showed none to involve gross rearrangements, although the same number of lethals, if it were produced in spermatozoa by X-rays giving the same mutation frequency, would usually include several rearrangements. All in all, then, there can be no question of the difference in the genetic action of ultra-violet and X-rays in *Drosophila*, or of the existence of a difference in the mechanism whereby the 'point changes' leading to gene mutations and gross rearrangements, respectively, are produced.

Spectrometric determination of relative intensities of different spectral regions in the case of the two

alternative filters indicated that approximately the same amount of genetic effect was produced by the two filters when the dosage between wave-lengths 280 and 300 m μ was held constant, even though in that case the Chance filter transmitted (during the total time it was used) 50 per cent more of the longer wave-lengths than the U.G.2. If confirmed, this would mean that wave-lengths longer than about 300 m μ were relatively ineffective genetically (cf. Noethling and Stubbe^{10,14} and Stadler and Uber¹⁵). This question is being investigated further.

It will be of especial interest to know whether or not ultra-violet light, as compared with X-rays, discriminates between the production of minute rearrangements and gene mutations. Work on this problem is now in progress.

The assistance of the Scottish Cancer Control Organization in furnishing funds for this investigation is acknowledged with thanks.

The Mathematical Association Annual Meeting

THE annual meeting of the Mathematical Association was held at King's College, London, W.C.2, on January 2 and 3. At the business meeting, Mr. W. C. Fletcher was elected president for the ensuing year and officers were elected as follows: *Treasurer*: Mr. K. S. Snell; *Secretaries*: Mr. G. L. Parsons and Mrs. E. M. Williams; *Librarian*: Prof. E. H. Neville; *Editor of the Mathematical Gazette*: Mr. T. A. A. Broadbent. Special reference was made to the work done for the Association by Miss M. Punnett, who retired from the office of secretary after twenty-seven years. Miss Punnett was elected a vice-president of the Association. A revised set of rules, proposed by Prof. E. H. Neville, was carried.

The report of the Council gives the number of members as 1,714 and refers to the activities of the branches. A new branch at Sheffield has recently been formed. Several sub-committees of the Teaching Committee are at present working on different aspects of mathematical teaching, including one on trigono-

metry and another on mathematics for evening technical students. The report further refers to the recently issued "Second Report on the Teaching of Geometry", to the Library and the Problem Bureau, and to the decision of the Council to recognize approved student societies as junior branches. A student society at Cambridge has already been recognized under this rule.

The presidential address was given by Mr. W. Hope-Jones of Eton College, who chose as his subject "Simplicity and Truthfulness in Arithmetic". His first plea was for 'checkability', and he claimed that a well-done piece of work is easier to check by reading it than by doing it again. He also criticized some current practices such as 'cancelling', undue use of improper fractions, loose wording notation in percentage examples and the 'unitary' method. He claimed that teachers were to blame for these defects, since boys have not enough ingenuity to invent their own bad methods, and he attributed

his own progress in arithmetic to avoidance of dodges for making easy things difficult. Finally, he dealt with tables, with special reference to difference-columns, and gave an instructive comparison of the relative accuracy of different methods of constructing and using these tables. The address was delivered in an extremely witty and amusing style, and was greatly appreciated by the crowded audience.

The next address was by Prof. W. L. Bragg, on "Crystallography". Prof. Bragg first dealt with the symmetry of patterns in two dimensions, and, having explained the division of two-dimensional patterns into cells, proceeded to enumerate the seventeen different types of symmetry, of which illustrations were given. He then considered space lattices in three dimensions and illustrated the fourteen distinct types, which give rise to 230 different varieties of three-dimensional symmetry. He illustrated this by reference to one particular group, namely, the space-groups of the orthorhombic lattice. Prof. Bragg concluded by explaining how these types of symmetry enter into crystal structure so as to give rise to the thirty-two classes of crystal symmetry. The lecture was illustrated by slides and was keenly followed by a good audience.

The proceedings of the second day were opened by Mr. A. Buxton, who spoke on "The Teaching of Applied Mathematics in Technical Colleges". He used the term 'applied' in its widest sense, as the students in such institutions require to learn mathematics in order to apply it to engineering, physical chemistry, optics, architecture, etc. The limited previous experience of these pupils and the small amount of time at their disposal (evening students outnumber day students by three to one), means inevitably that the content of the syllabus has to be reduced to a minimum. 'Short cuts' have to be developed wherever possible and formal proofs to a large extent have to be omitted. Mechanics has proved especially difficult, but Mr. Buxton showed how some of the difficulties can be overcome by the use of accurate graphical work and concluded with an interesting example of the use of a velocity diagram to find the velocity of a carried point.

Mr. H. W. Newton gave an interesting illustrated lecture on "Greenwich Observatory: some Aspects of its Work". He showed by a short historical sketch how the work of the Observatory has been mainly concerned with positional astronomy in accordance with its original charter and referred to the discovery of aberration as a result of this work. Illustrations were shown of the older buildings and instruments and also of the instruments now in use, especially those used in the determination of time by observing the transit of a star, a process which Mr. Newton described in some detail, and in stellar photography. He concluded his lecture by a reference to some of the work which has been done in observing the surface of the sun and in photographing, in hydrogen light, bright eruptions and other markings upon it.

The principal speakers in the discussion on the "Second Report on the Teaching of Geometry" were Mr. A. W. Siddons, Miss W. M. Lehfeldt (deputizing for Miss M. A. Hooke) and Mr. H. Beardwood. In the main, all these speakers commended the report. Mr. Siddons referred to some points with regard to the use of small letters to denote angles and to the method of distinguishing the cases of congruence. He also recommended that the idea of similarity should be introduced at an early stage. Miss Lehfeldt

emphasized the necessity of a knowledge of geometrical facts rather than their proofs, and also referred to the need for partnership between the teacher and the class in 'rider' work. She referred to the section on the relation between geometry and geography, a region in which valuable chances of illustrating mathematical principles are frequently missed. Mr. Beardwood criticized the omission of any reference to the inter-relation of geometry and trigonometry, and the absence of any special suggestions for the geometry desirable for very weak pupils. In the subsequent discussion, valuable points were raised by Messrs. Kenworthy-Browne, Inman, Sheppard, Hope-Jones, Kearney, Snell, Roebuck, Broadbent and W. C. Fletcher.

The afternoon session was opened by Mr. W. L. Ferrar, who spoke on "Algebra in the Higher School Certificate". He stated that the ideas of general convergence of series and sequences are, in his opinion, introduced too early in the course, a procedure which leads to an excessive reliance on the 'ratio test'. The principal use of convergence at this stage should be in connexion with the series for $\log(1+x)$, e^x and $(1+x)^n$, and for these series *ad hoc* methods involving integrals should be used. He next referred to defects in the understanding of the logic of algebra, as, for example, the distinction between theorem and converse, and muddled ideas on the nature of proof by induction, a process in which the fundamental principles are easily obscured by the manipulations involved. He also dealt with some points concerning difference equations. The present situation in regard to higher algebra is, he said, becoming difficult, especially for the examiner. The casting out of some of the old items in the syllabus and the introduction of some new ones have reduced the syllabus to a collection of odd and unrelated scraps. He suggested the formation of a committee to put forward the views of the Association in this matter.

At the final meeting, Lord Stamp spoke to a large and interested audience on "Education and the Statistical Method in Business, with Special Reference to Railway Statistics". Lord Stamp considers that education can do more to prepare the student for business life, and gave a valuable list of topics of a statistical nature which might with advantage be introduced in the ordinary teaching of mathematics. He first referred to averages—with their adjuncts the standard deviation, the mode, the median and the quartiles—and to moving averages, in regard to which he made some useful suggestions about the choice of a scale, and to percentages, urging the use of examples from social and economic sources. He next considered various graphical methods to which pupils might be introduced, with some cautions as to possible errors. The ideas involved in the use of samples and of index numbers might also be introduced and explained. He referred also to price levels, correlation coefficients, graphical methods for eliminating short-period fluctuations, and units of cost and performance. A number of interesting examples were quoted in connexion with some of the above items, such as weighted averages and operating ratios. Lord Stamp concluded with some remarks on the difficulty of choosing a useful unit in which some types of performance could be measured, and illustrated his remarks by a further reference to railway problems.

A fuller account of the proceedings of the meeting will appear in forthcoming issues of the *Mathematical Gazette*.

The Physical Society Annual Exhibition

YEAR by year the Physical Society holds an exhibition of scientific instruments and apparatus, which has now grown so that this year—the twenty-ninth—111 individuals and firms describe their exhibits in a catalogue of more than two hundred pages. The exhibition is divided into two sections, one a Trade Section where various physical instruments may be inspected, and the other a Research and Experimental Section.

The Trade Section is of great value to the prospective purchaser of physical apparatus, since it gives him the opportunity of comparing alternative makes of instrument at one time. This aim would be facilitated by a better index to the catalogue so that, for example, gas-analysis apparatus and carbon dioxide and oxygen meters came under a common heading. One reflection that must strike the visitor to this assemblage of instruments is the immense variety of uses to which electronic devices are now put in commercial and industrial instruments. British industry also responds quite rapidly to new needs imposed by legislation or by the political situation, and A.R.P. is mentioned in several of the catalogue descriptions. The Factories Act of 1937 has led to a spurt in the output of photometric equipment, much of which utilizes photo-electric cells, thereby obtaining rapid response and the advantage of a wide range; one instrument can read from extremely low values, of the order of 0.001, up to 100 ft.-candles. The photo-electric cell finds application also in temperature control. For this purpose, the pointer of the instrument which indicates the temperature to be controlled casts a shadow on a selenium cell, and any deviation from its pre-selected position operates the cell and hence a control to restore the temperature to its original value.

The report of the Ministry of Transport Committee on traffic noise is doubtless a contributory factor to the activity shown in the production of noise-meters and other acoustic instruments, of which many were on view. The high-vacuum pump has long been an important tool both in the physical laboratory and in technical processes, and it was interesting to see a new diffusion pump in which the oil or mercury had been replaced by an organic fluid of very low vapour pressure, and means had been provided for continuous self-purification of this fluid, thus avoiding the accumulation of condensable vapours in the pump system, and permitting the attainment of very high vacua, whatever the composition of the gases being removed.

Turning attention now to the Research Section, it is impossible to deal in detail with all the exhibits, which range over almost the whole field of pure and applied physics. Some of the best, such as the calorimetric equipment of Dr. W. D. Wright and Mr. H. V. Walters, and the investigations on dielectrics by the staff of the British Electrical and Allied Industries Research Association, were of rather specialist character. An exhibit of more general interest was provided by the Physics Department of the National Physical Laboratory, and illustrated forcibly the great variety of problems dealt with at the Laboratory. The acoustics exhibit in-

cluded the analysis of noise, where visitors could see the intensities of the various frequency components in a complex sound as a linear spectrum in a cathode ray oscillograph, as well as the wave-form of the same sound in a neighbouring cathode ray tube; models also demonstrated how the transmission of noises in a building can be diminished. Other exhibits showed the work on radium and X-rays, whilst a set of illuminated models of crystal lattices was attractive, even if it conveyed little new information.

Many visitors were attracted by the exhibit organized by the Scientific Computing Service, Ltd., where in addition to a display of calculating machines, there was a new 135-character typewriter, and an interesting survey of the whole history of the production of a mathematical table, from the first calculations to the final printing. Pure mechanics is somewhat out of fashion, but Messrs. W. and T. Avery, Ltd., showed that it still has points of interest, in an exhibit which showed various little-known statical principles which find application in weighing mechanisms. Messrs. H. A. Boot and A. H. Knight showed a small model of the electrostatic generator used in nuclear research by Prof. van de Graaff, which operates by collecting charges from a moving insulated belt and allowing these to accumulate within a metal sphere. The generator shown could furnish a current of 30 μ a., the maximum voltage being 250,000.

Two ingenious experiments for the school laboratory were shown by Mr. W. O. Clarke, in one of which Planck's constant is determined with apparatus no more complicated than a commercial photometer and an incandescent lamp with electrical measuring instruments, and the other enables the specific heat of air to be measured by using a hot-air blower as the basis of a continuous-flow calorimeter.

Among the many novelties shown by the Research Laboratories of the General Electric Co., Ltd., was an apparatus for measuring the mean strength of a magnetic field by amplifying the alternating E.M.F. obtained when a small coil is rotated in the field. They also demonstrated a method by which the intensity of the light from a photo-flash lamp (which reaches its maximum in only 0.05 sec. from ignition) can be studied in detail as a function of time.

In a demonstration by Drs. E. E. Widdowson and S. J. Gregg, multi-molecular layers of barium stearate were being built up by the successive deposition of mono-molecular layers. A striking feature is the vivid colours, changing rapidly with the number of layers, which are seen when the multi-molecular film is viewed by polarized light. The behaviour of lamp filaments and their mountings under vibration must be important to the designer and manufacturer, and many visitors found a stroboscopic picture of this behaviour to be both attractive and informative. This was one of several items included in the exhibit of the Research Laboratories of the British Thomson-Houston Co., Ltd. Finally, many lecturers will be grateful for the simple method demonstrated by Prof. J. D. Bernal, whereby the relation between the Laue diagram and the Bragg reflection patterns can be shown visually.

Exhibition of Scottish Art

VISITORS to the present exhibition of Scottish painting, sculpture, furniture and other work of art, on loan from various public and private sources, at the Royal Academy, London, are likely to feel the force of the complaint that Scotland was not adequately represented in the exhibition of British art held some winters ago. Certainly men of science should find much there to interest them in the healthy realism displayed in many fields.

The exhibits, which exclude the work of living artists, range mainly over the seventeenth, eighteenth and nineteenth centuries, and dealing largely with Scottish subjects, clearly reflect national character, customs and influencing geographical environment. There are portraits of a small number of men of science, including Murray's "Edmond Halley" (21), Raeburn's "Professor John Robison" (84), an early secretary of the Royal Society, Shannan's "Lord Kelvin" (395) shown bare-headed in academic robes, and Walton's "J. G. Bartholomew, LL.D." (538) in doctor's robes with hand on globe. But amid the vast array of portraits by Raeburn, Ramsay and others, attention may well be directed, also, to Raeburn's magnificent rendering of "Sir Walter Scott" (83) sitting outside Hermitage Castle with the mountains of Liddesdale in the background, to Macnee's huge canvas "The Rev. Ralph Wardlaw, D.D." (196), outstanding as a study in force of character and ministerial type, and to the near-by fine portrayal of Macnee's own daughter "Lady in Grey" (199). In group portraiture those who look for expression of what is typical in national culture will appreciate Lorimer's "Ordination of Elders in a Scottish Kirk" (545).

Landscape, which notwithstanding its prominence in literature, arose in art rather later in Scotland than in England, is quite well represented in the collection, and shows an interesting association with group portraiture. Of this association there are two outstanding examples: one, Guthrie's large canvas "A Highland Funeral" (513), where the assembly appears in snow-clad moorland outside a stone cottage; the other, the same painter's "Schoolmates" (525), wherein two girls and a boy, of quite striking physical beauty, are wending their way to school in a late autumn landscape. William McTaggart, perhaps the most original of the Scottish landscape painters, has almost a gallery to himself: "Away o'er the Sea", "The Storm", "The Wind in the Grass", "The Wave", "Blithe October", "April Snow" and "Spring" being a few of his contributions. A characteristic of this artist is his habit of putting a group of children in the foreground of his rural or seashore pictures, and, though in some cases the figures are not very successfully delineated as elements in the landscape, in others the effect is admirable. Thus in "Spring" (384), the blue range of hills in the background, the cottage with trees in the middle distance, the sheep, and the children plucking wild flowers in front, are all in perfect relationship, constituting a typical scene of the Lowlands of Scotland. In this characteristic, McTaggart shows himself in spirit a true Wordsworthian. David Farquharson's "River Road, Strathdon" (295) is a summer scene showing shepherd and flock and pouring rain over a distant range of mountains, whilst Joseph Farquharson's "Stormy Blast" (296), one of this painter's famous snow scenes, is a fine piece of impressionism, illustrating the

smothering effect of snow upon a moorland flock of sheep. The omission of a few pictures of the type of "Stormy Blast" from any exhibition of Scottish landscape would be unthinkable, for the imagery of snow is somewhat obtrusive in the literature of Scotland and deeply rooted in one's sense of the wild beauty and romantic history of that rugged northern land.

In pure landscape, however, at any rate as regards Scottish scenery, the masterpieces are McCulloch's famous "Glencoe" (177) and Peter Graham's "Wandering Shadows" (238). In "Glencoe" there is massiveness both of mountains and of mountainous cumulo-nimbus clouds so closely interlocked that in one place the painter rightly leaves the spectators in doubt to which element a dark rugged outline belongs. Pine trees stand at intervals down the glen, there are stags in the foreground, and in the left-hand corner, half hidden in a gloomy ravine, lies a sullen tarn. In "Wandering Shadows" the painter of the "mountain and the flood" has left us a superb piece of chiaroscuro. The nearer mountain flank is gloriously lit in contrast with the farther range, which is steeped in intense blue-black shadow. Mists are coursing the mountain sides so realistically that one almost sees them driving—a sure indication of good work. In the foreground a man is fishing in the torrent, and there are sheep grazing amid lichen-crusting boulders showing just the right amount of detail.

In sculpture, mention may be made of a "Symbol Stone" from Orkney with a design the meaning of which is lost, but known to date from Early Christian times, and also of a kid standing on a rock—reflecting a Highland background. In the vestibule, the visitor is greeted, symbolically, by a statue of John Knox with Bible in hand.

Science News a Century Ago

The Institution of Civil Engineers

At the annual general meeting of the Institution of Civil Engineers held on January 15, 1839, the president, James Walker, being in the chair, the report for the year was presented. At this time no fewer than nine members of the Council were fellows of the Royal Society, J. Walker, W. Cubitt, Bryan Donkin, Joshua Field, H. R. Palmer, I. K. Brunel, Joseph Locke, George Lowe and John Macnail. One of the problems the Council had considered was that of qualification for membership. "The objects of the civil engineer," the Council said, "were defined by charter and in guiding them in their task they had adhered closely to the two following conditions: (1) that the party should have been regularly educated as a civil engineer according to the usual routine of pupillage, and had had subsequent employment for at least five years in responsible positions, resident or otherwise, or (2) that he should have practised on his account in the profession of civil engineer for five years and have acquired considerable eminence therein. In earlier days the force of genius alone was sufficient to place the individual in that position of professional eminence which commenced with a Brindley and a Smeaton, and was in our own time exemplified in a Rennie and a Telford." To such, of

which there are many illustrious examples still living, the second condition was strictly applicable."

The Interior of the Earth

At a meeting of the Royal Society held on January 17, 1889, W. Hopkins read his second paper on the state of the interior of the earth, entitled "The Phenomena of Precession and Nutation, assuming the Fluidity of the Interior of the Earth". For the purpose of his investigation Hopkins assumed the solid shell of the earth to be bounded by a determinate inner spheroidal surface of which the ellipticity is equal to that of the outer surface and the shell and fluid to be homogeneous and of equal density. Having given the results of his inquiries as affecting precession, and lunar and solar rotation he said that "the pole of the earth would have a small circular motion, depending entirely on the internal fluidity. The radius of the circle thus described would be greatest when the thickness of the shell should be least; but the inequality thus produced would not, for the smallest thickness of the shell, exceed a quantity of the same order as the polar nutation, and for any but the most inconsiderable thickness of the shell, would be entirely inappreciable to observation."

English Medical Society in Paris

THE *Lancet* of January 20, 1889, contains the following information: "An English medical society has recently been established in Paris and already includes on its list between 90 and 100 members. At one of the last meetings Sir R. Charnside was elected president and J. Godfrey, Esq., vice-president for the present year. The Society holds weekly meetings at which papers are read upon medical subjects and discussions take place in the *English language*. These meetings are peculiarly interesting, as medical men from London, Edinburgh, Dublin and different parts of America join in the proceedings, as well as some of the 'externes' and 'internes' of the Parisian hospitals. The Society has established a reading room for the English and French periodicals, and the nucleus of a permanent library is already in existence."

Geodetical Work at the Cape of Good Hope

In his "Autobiography", under the year 1839, Airy wrote, "I had much work in connection with the Cape of Good Hope Observatory, chiefly relating to instrumental equipment and to the geodetical work. As it was considered advisable that any base measured in the Cape Colony should be measured with compensation bars, I applied to Major Jervis for the loan of those belonging to the East Indian Survey, but he positively refused to lend them. On Jan. 20th I applied to Col. Colby for the compensation bars of the British Survey, and he immediately assented to lending them. Col. Colby had suggested to the Ordnance Department that Capt. Henderson and several sappers should be sent to use the measuring bars and it was so arranged. It still appeared desirable to have the command of some soldiers from the Garrison of Cape Town, and this matter was soon arranged with the Military authorities by the Admiralty."

The geodetical work at the Cape included the remeasurement and extension of Lacaille's arc, and it was carried out by Sir Thomas Maclear, the Astronomer Royal at the Cape, the results being published in 1866, edited by Airy.

Societies and Academies

London

Royal Society (*Proc. A*, 169, 149-289; 1938).

O. K. INGOLD: Structure of benzene (Bakerian Lecture).

W. F. HILTON: Photography of airscrew sound waves.

D. H. EVERITT and W. F. K. WYNN-JONES: Dissociation of the ammonium ion and the basic strength of ammonia in water.

H. S. W. MASSY and R. A. BUCKINGHAM: Low temperature properties of gaseous helium.*

J. N. AGAR and F. P. BOWDEN: Kinetics of electrode reactions (1 and 2).

R. G. ATOMIK, N. S. BAYLISS and A. L. G. REES: Effect of solvents on the continuous absorption spectrum of bromine.

T. E. ALLIBONE and J. M. MEEK: Development of the spark discharge (2).

S. O. CURRAN, P. I. DINE and V. PETRÁŤKA: Excitation of γ -radiation in processes of proton capture by light elements.

Paris

Academy of Sciences (*C.R.*, 207, 1137-1268, Dec. 12, 1938).*

H. BRUCK: Extension of the $1^1P_1 - m^1S_0$ of zinc.

M. PARODI: Spectra of some derivatives of methane in the far infra-red.

L. MONTAUDO: Absorption and fluorescence spectra of pigments from the St. John's wort of the Mediterranean basin (*Hypericum crispum*). The *Hypericum* from Tunis, which often poisons animals, has different pigments from the European *Hypericum*.

J. DUBREUIL: Absorption spectra and chemical constitution of Sauton's liquid cultivated in tubercle bacilli B.C.G.

G. EMBRECHT: Production of iodic anhydride by photo-oxidation of organic oxides; photo-oxidation of iodoform and of solid carbon tetraiodide.

H. HUTUBET, MILLE, Y. CAUCHON and MME. S. COTELLE: Spectroscopic determination of the atomic number of polonium. The investigation shows that the detection of elements by their X-ray spectra is much more sensitive than was believed; the radiations detected in this case are those to be expected from an element of atomic number 84.

A. CLAUDE: Fluorescent tube-lamps functioning with the usual distribution voltage.

M. BRUTZOUS: A thermochemical constant and its relations with electronic energy values.*

R. ENGELAND: A new form of stereo-isomerism and an unknown form of glycooll: attempt at a theoretical interpretation.

V. AUGER: Two new molybdic acids.

R. CHAUVENET: Combinations of zinc nitrate and of alkaline nitrates.

A. MORETTE: The system iodine-vanadium: vanadium di-iodide and tri-iodide.

G. COURTOIS: Preparation of anhydrous sodium sulphide.

O. DUFRASSE and M. GERMAN: Study of the mechanism of dry extinction by dusts; nitrate, chlorate, perchlorate of potassium and other bodies which support combustion as extinguishers of flames.

*Continued from page 89.

P. GRAMMATIKAKIS: Action of organomagnesium mixtures on the benzylamines: preparation of secondary amines of the type $\text{Ar}(\text{R})\text{CH}_2\text{NH}(\text{CH}_2)_n\text{C}_6\text{H}_5$.

D. DUVEN and A. WILHELM: Synthesis of tetraphenyl-2, 6, 10, 12 bis-(diphenyl)-9, 11-naphthacene and its photo-oxide.

M. TUOT: Interpretation of secondary reactions observed in the course of the condensation by organomagnesium of ketones and of esters of the aliphatic series: theory.

Mme. R. DUBREUIL, L. DONCEUX, H. VAUTRIN and L. DUBREUIL: The nummulitic of the eastern slope of the Anti-Libanon (region of Damascus, Syria).

Mme. A. VASSY and E. VASSY: Daily variations of the mean temperature of the atmospheric ozone.

G. LEMOIN: Post-glacial forest history in Lower Normandy after pollen analysis of the peat-bogs.

J. MOTTE: Evolution of the nuclei of the inter-nodal cells of *Chara foetida*.

Mme. I. MICHALSKA and F.-X. SKUPNIECKI: Ecological researches on *Polysphondylium pallidum* Olive, *Polysphondylium violaceum* Bref., *Dictyostelium mucoroides* Bref.

Mlle. J. MANUEL: Formation of the ascus of *Nematosporea Coryli*, after a sexual phenomenon.

P. RIQU and G. DELORME: Distribution of manganese and of iron in the ashes and elms of the Province of Quebec.

R. ULRICH: Variations of the reactions to superficial lesions as a function of their surface (fruits of *Iris pallida* Lam.).

V. VINCENT and P. BOISCHOT: Nature and composition of the organic matter of the phosphates of North Africa: the phosphate of Gafsa.

J. GEORGEVITCH: *Sphaeractinomyxon danicos* n.sp., an actinomyxidial parasite on an oligochaete of Lake Ochrida.

RAYMOND-HAMET: Major hypotensor and sympathetolitic effects of hydrocinchonidine.

Mlle. P. BEETHIE: Coefficient of magnetization and electric sign of solutions of haematin and of acethaemin.

B. LUYET and G. THORNES: Revival of muscle fibres vitrified in liquid air.

M. RANGIER and P. DE TRAVERSE: Mode of formation and constitution of urinary scatole red.

G. RAMON: Some methods for the rapid and intensive production of diphtheria and tetanus antitoxins in the horse.

A. SARTORY, J. MEYER and D. SCHMUTZ: Conditions favouring bacterial growth by preliminary introduction of vitamins B₁ and B₂ combined and in varied doses, into the culture medium.

J. RIGNIER and Mlle. S. LAMBIN: Study of microbial growth as a function of the quantity of nutritive substance in culture media.

J. CHAUSSIN and L. LEBONNE: Study of the variations of phthalein and formol acidities of urine during 24 hours of eight diabetics.

Sydney

Royal Society of New South Wales (*J. and Proc.*, 72; 1937-38).

S. B. COHEN and F. M. QUODLING: An X-ray examination of chillagite. From oscillation and powder photographs (copper $K\alpha$) chillagite has been found to have cell dimensions in close agreement with those of wulfenite and stolkite and the same

number of molecules per cell (4). Chillagite is regarded as a mixed crystal of these two substances, not as a distinct mineral species.

J. G. CHURCHWARD: Studies on physiological specialization of the organisms causing bunt in wheat, and the genetics of resistance to this and certain other wheat diseases. (2) Genetical studies. In a wheat cross, Federation $\times$ Hope, studies were made in the field and greenhouse on the inheritance of resistance to bunt, to flag smut, to two races of stem rust, and certain morphological characters. In addition to the single factor for resistance to bunt, there are several modifying factors acting in this cross. With two exceptions, the inheritance of the remaining characters is explained by simple Mendelian hypotheses.

S. W. CARRY and W. R. BROWN: Review of the carboniferous stratigraphy, tectonics and palaeogeography of New South Wales and Queensland. A scheme of subdivision is proposed for the Lower and Middle Carboniferous of New South Wales, embodying recognition of the fact that freshwater and marine sedimentation proceeded simultaneously in Viséan time. Many, if not all, the known occurrences fit into this scheme. Correlations are also instituted with Queensland. The earth-movements which determined loci of sedimentation and affected the sediments after deposition are enumerated—the late Devonian Kanimbla, the epi-Burindi Drummond and the late Permian Hunter-Bowen orogenies, with minor vertical movements at the close of Lower Burindi and Upper Kuttung times.

ADOLPH BOLLIGER and A. L. CARRODUS: Changes in and around the pouch in *Trichosurus vulpecula*, as occurring naturally and as the result of the administration of oestrone. The sexually immature Australian opossum (*Trichosurus vulpecula*) shows no pigmentation in its undeveloped pouch, and the hair on its ventral aspect is usually white. Injections of oestrone bring on development of the pouch, mammary glands become evident, and the nipples undergo hypertrophy. Simultaneously a pigment is secreted within the pouch and forms a dark brown deposit, while the hairs within the pouch as well as those around it become stained from a yellow to a dark golden brown. Similar changes were observed to occur under natural conditions, and they are considered to be connected with the sex life of the animal.

Washington, D.C.

National Academy of Sciences (*Proc.*, 24, 497-523, Nov. 15, 1938).

R. A. BRINK and D. C. COOPER: Partial self-incompatibility in *Medicago sativa*. Pollen is less efficient in self-pollinations than in cross-pollinations, while ovules containing inbred embryos show a greater tendency to collapse than those from cross-fertilization.

J. G. CARLSON: Mitotic behaviour of induced chromosomal fragments lacking spindle attachments in the neuroblasts of the grasshopper.

O. STOCK: A titanothere from the type Sespe of California.

BARBARA S. BURNS: Autosomal linkage in man: the recombination ratio between congenital tooth deficiency and hair colour.

R. COURANT: Remarks on Plateau's and Douglas's problem.

Forthcoming Events

[Meetings marked with an asterisk are open to the public.]

Monday, January 16

UNIVERSITY OF LEEDS, at 5.15.—Dr. J. Hammond, F.R.S.: "Fertility and Growth in Domestic Animals" (Oliver Behrens Lectures. Succeding lectures on January 30, February 20 and 27 and March 13).*

Tuesday, January 17

EUGENIC SOCIETY (at the Royal Society), at 5.15.—Dr. Felix Tietze: "Eugenic Measures in the Third Reich".*

UNIVERSITY COLLEGE, LONDON, at 5.30.—Sir Ambrose Fleming, F.R.S.: "History of the Thermionic Valve at University College".*

ILLUMINATING ENGINEERING SOCIETY, at 7.—Discussion on "Lighting in Relation to Air Raid Precautions".

Wednesday, January 18

ROYAL MICROSCOPICAL SOCIETY, at 5.30.—J. E. Bernard, F.R.S.: "Towards the Smallest Living Things" (Presidential Address).

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Dr. B. A. Keen, F.R.S.: "What Happens to the Rain?"

ROYAL SOCIETY OF ARTS, at 8.15.—H. L. Kirke: "Recent Progress in Television".

Thursday, January 19

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY (ROYAL SCHOOL OF MINES), at 5.30.—Dr. J. Hammond, F.R.S.: "Animal Breeding" (succeding lectures on January 26 and February 2 and 9).*

Friday, January 20

ROYAL INSTITUTION, at 9.—Dr. Fraser Darling: "North Rona: a North Atlantic Island".

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

LECTURER IN CHEMISTRY at the Kingston-upon-Thames Technical College—The Principal (January 14).

CHEMIST at the Royal Gunpowder Factory, Waltham Abbey or the Royal Ordnance Factory, Irvine—The Under-Secretary of State (O.S.), War Office, London, S.W.1 (January 20).

ASSISTANT CIVIL ENGINEER at the Royal Ordnance Factory, Bishopston, Renfrewshire—The Superintendent, Royal Gunpowder Factory, Waltham Abbey (January 20).

UNIVERSITY READER IN METEOROLOGY in the Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, W.C.1 (January 20).

ASSISTANTS (grade III) in the Meteorological Office—The Under-Secretary of State, S.S.B. (Met.), Air Ministry, Admiralty House, Kingsway, W.C.2 (January 31).

LECTURER IN BIOLOGY in the Central Technical College, Suffolk Street, Birmingham, 1—The Chief Education Officer (January 31).

LECTURER IN MINING in the University of Sheffield—The Registrar (February 4).

LECTURER IN BIOCHEMISTRY in the Otago University Medical School—The High Commissioner for New Zealand, 415 Strand, W.C.2 (March 23).

LECTURER IN ENGINEERING in the Swansea Technical College—The Director of Education, Education Department, Guildhall, Swansea.

Planning for Constructive Defence

THE stress rightly been laid in recent months upon moral rearmament is essentially the recognition that there must be some underlying moral basis and explicit code of values upon which we can take our stand in working towards a more tolerable human society. In addition, however, we have been brought to realize the importance of visualizing the national economy and resources as a whole. The defence policy which is now imperative cannot be limited to the negative aspect of armaments and naval, military or air force organization. In addition, it must embrace positive effort devoted to removing causes of international friction and improving international relations, and also much of the work now directed to improving industrial efficiency, national health, social and economic conditions generally. It involves essentially industrial, social and economic strategy and tactics no less than naval or military strategy and tactics.

The dominant factor in determining this profound change has, of course, been the development of air transport as a weapon of war. In the face of this threat, the industrial cities of to-day have to develop the appropriate defensive measures in much the same way as the fortified city of the Middle Ages was developed to meet the military dangers of those days. The essential problem is indeed that of so planning our industrial, social and economic life as to secure adequate protection against sudden aggression, while preserving, under normal conditions, the maximum freedom of enterprise and activity consistent with rapid adjustment to the demands of a time of national emergency. We have to develop under the conditions of to-day a society that can mobilize in response to the threat of war as instantly and effectively as the burghers of the medieval town.

This aspect of planning was frankly recognized in the recent presidential address to the Town Planning Institute delivered by Mr. J. E. Acfield, who stressed the significance of the necessity of considering not only the risks of air attack but also those questions of location of industry, transport and the like which have to be taken into account in planning and may be equally determined by defence policy. He pointed out that the recent emergency had decisively emphasized the necessity for a National Advisory Board recommended in the report of the Town Planning Institute, and directed attention to the importance of recognizing trends in population occasioned not only by location of industry but also by changes in age distribution and the like due to the declining birth-rate. Similarly, a resolution on the planned control of the growth of London was moved by Sir Raymond Unwin at a conference of the Garden Cities and Town Planning Association. The resolution contemplates an authority which would control the location of new industries, preserve the remaining country within reach of London, guide development to existing smaller towns or well-designed new towns in the region and create a long-term plan for re-development in the centre. In discussing the project, Sir Raymond referred to the added urgency given to such problems by the necessity of protection from air raids, and the way in which planning could minimize risks.

The need for concerted policy in this matter of defence has been significantly enforced by investigations in widely different fields. Evidence submitted from time to time during the past year to the Royal Commission on the Distribution of the Industrial Population has indicated the necessity for some State control in this matter from the

point of view of the most effective utilization of national resources, no less than from considerations of defence, and the report when it appears may well be expected to make some emphatic pronouncement on this point. The appointment of this Commission itself was largely due to the recommendation of Sir Malcolm Stewart's third report as Commissioner of the Special Areas, that the further expansion of industry in Greater London should be controlled to secure a more even distribution of production in which the Special Areas might share.

The same point of view has been taken by Sir Malcolm's successor, Sir George Gillett, who in his first report* insists that consideration of the social as well as of the economic effects of the transference of industries lies near the root of the problem of the Special Areas. In his view, the Government cannot, especially since the introduction of tariffs and quotas, evade all responsibility for the location of industry. Social and strategic, as well as economic, causes are fast impelling the abandonment of the *laissez-faire* doctrine in this matter.

Even more emphatically, however, have the events of the recent national emergency endorsed Sir Malcolm Stewart's argument about control of the location of industry in Greater London. The Committee on Evacuation was appointed in May 1938, but the report itself was only published in November†, when the state of emergency was over. No reader of this report can be in any doubt as to the desirability of planning industrial location in future so as to diminish its vulnerability, or of the dangers to which unrestricted development in the past has now exposed us.

The difficulties with which evacuation is attended are made perfectly plain by the Committee, which considers that, none the less, the whole issue in any future war may well turn on the manner in which the problem of evacuation from densely populated areas is handled. Evacuation plans are no substitute for measures of active and passive defence, designed to enable production to be maintained in time of war in the industrial areas, but some measure of evacuation of non-essential persons from the principal industrial areas must be faced both on the grounds of humanity and to relieve the situation in congested industrial areas.

Indeed the country will not be fully prepared against attack until the necessary organization has been established and schemes of evacuation worked out.

In a covering memorandum to the report, the Home Secretary, Sir Samuel Hoare, indicates the Government's approval of the recommendations of the Committee and particularly its concurrence in the principle of voluntary but organized evacuation, as well as in that of accommodation of refugees under powers of compulsory billeting. While, however, the report clearly shows that a scheme based on these lines is perfectly practicable and that adequate transport facilities appear to exist, on many points of detail very much remains to be done, particularly in regard to billeting, if the anomalies and even absurdities exposed during the crisis of September last are to be avoided. Something more than a mere count of houses or population is required if billeting is not to become farcical or even have alarming repercussions on the health of the community. Again, evacuation can only be regarded as a palliative, and the recognition of its present necessity should stimulate efforts directed to eliminate that necessity in future, whether by wiser location of industry or by the planning of towns and industrial areas so as to render them less vulnerable.

It should not be forgotten, moreover, that evacuation plans cannot be drawn up in isolation. They must form part of a considered and co-ordinated plan for national defence. Unless, for example, plans conceived in peace-time take into account the probable effect of emergency demands upon the population, not merely of the areas to be evacuated but also of those into which evacuation is to take place, the whole plan may break down at important points, or place intolerable strain upon particular localities or communities. Evacuation, in fact, must be considered with the Government's plan for a national register, whether voluntary or otherwise, which undoubtedly should yield important evidence to test the soundness of the evacuation plans in regard to district details. Moreover, man-power policy must involve more than the institution of a system even for securing the best utilization of the available resources in special skill and training or professional and technical knowledge. It must also have regard to measures which will ensure the continuance of the supply and that its quality is maintained.

From whatever angle therefore this question of national defence is approached, the supreme

* Report of the Commissioner for the Special Areas in England and Wales for the Year ended 30th September, 1937. (Cmd. 5593.) Pp. xii+209. (London: H.M. Stationary Office, 1938.) 3s. 6d. net.

† Report of the Committee on Evacuation: with a Covering Memorandum by the Secretary of State for the Home Department. (Cmd. 5837.) Pp. iv+29. (London: H.M. Stationary Office, 1938.) 9s. net.

importance of a definite and co-ordinated national policy which takes account of all the factors involved and transcends sectional interests or prejudiced views is unmistakable. The danger at the present moment is that the impulse towards effective planning provided by the recent emergency may die out before it has been turned to tangible purpose. Further, in the absence of the elaboration and enactment of a definite policy of defence, private or sectional interests may embark on courses or policies which are inconsistent with the public good; while public authorities left without adequate guidance, whether they do nothing but continue along existing lines or follow some unsatisfactory line, may increase unwittingly the obstacles to the execution of a boldly conceived national plan.

In the face of this complex and difficult situation with its urgent call for a national plan, the opportunity which a defence policy affords for constructive effort should not be overlooked. National defence has qualitative as well as quantitative aspects. It must not merely provide against external threats to the existence of the nation. It must make positive contributions to its welfare. A policy for defence must take account of social welfare as well as of armament production and civil defence. National fitness in the widest sense is an indispensable element in national defence. Wisely conceived, a policy for defence will take account not only of physical training, nutrition, overcrowding, unemployment and other factors affecting the health of the nation. It will have regard also to many of the amenities of life which determine the mental and moral as well as the physical fitness of the people. Planning, whether

civic or industrial, must be conceived not merely to provide more effective protection against attack and more efficient use of the man-power and material resources of the nation, but also to preserve the amenities of countryside, flora and fauna. It involves a land policy which will safeguard no less against the blunders of the past which have increased vulnerability than against the further destruction of national assets and amenities. It may well involve, too, an examination of the functions of local government and national administration and of the size of operating areas, if causes of inefficiency are to be eliminated and obstacles to a national policy overcome.

Nothing would indeed be more short-sighted than a policy for defence which restricted or warped educational development or those ideals of individual freedom of thought and criticism which are rightly cherished in a democracy. A defence policy must appeal to the highest ideals if it is to claim support, and for this reason alone it will be inadequate unless it offers also constructive effort towards international peace and good will, by working towards the removal of causes of international friction. Here indeed is work for education both within and without the frontiers of a State. The development of a national defence policy on such lines under the stress of the recent emergency may give us the stimulus to a plan and a concentrated effort which will overcome alike the obstacles and the threats which sectional or private interests have so long opposed in such diverse fields as road transport, building, town planning, national parks, nutrition and health to measures the desirability of which in the national interest has long been beyond dispute.

British Agriculture

British Agriculture:

the Principles of Future Policy. A Report of an Enquiry organized by Viscount Astor and B. Seeböhm Rowntree. Pp. xx+469. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1938.) 15s. net.

THIS book is the report of an inquiry, organized by Viscount Astor and Mr. Seeböhm Rowntree, into the economic structure of British agriculture. It deals comprehensively with the

main aspects of the agricultural problem, and although its chapters are rather unequal in quality, it provides a valuable addition to agricultural literature.

The volume is divided into five parts. In the first of these the authors examine the possibility of increasing agricultural production by curtailing imports. After considering the issues involved, they consider that protective measures should be limited so far as possible to securing reasonable stability for home producers and to averting

disastrous price fluctuations. In their opinion the future development of the industry should depend on increased production of 'health foods'; such as milk and vegetables, for which farmers in Great Britain enjoy natural protection. They also consider that the industry should be assisted by the State in ways likely to promote the supply of these foods, to increase efficiency in both production and marketing, and to preserve the fertility of the soil. They then examine the economic causes underlying the changes which have occurred in agricultural production in Great Britain during recent years.

Part 2 discusses in detail the economics of crop production, and contains chapters on grass, grain crops, roots and sugar policy, feeding stuffs, potatoes and hops, vegetables and fruit. Part 3 is concerned with livestock and livestock products. In this section there are chapters on cattle, sheep, pigs, poultry, milk production, and milk marketing. Part 4 deals with the personnel and organization of the industry, and discusses the problems of agricultural labour, smallholders, farmers, agricultural credit, landlords, and research, education and advice. Each of these chapters is packed with interesting information, although sometimes they are marred by wrong emphasis and factual inaccuracies.

In this respect, the chapter on milk is particularly unfortunate. For example, the effects of depreciation on milk production costs are considerably exaggerated, and the question of increasing the herd life of the cow, on which great emphasis is placed, is less important than that of increasing its general health. Of course the first condition is likely to follow from the second; but, owing to the more rigorous selection necessary in an attested herd, it is improbable that depreciation will be reduced, at least in the early stages of a cleaning-up policy. Moreover, depreciation at the moment represents only some 10 per cent of the total costs of milk production, or 1d. per gallon of milk produced. Again, there is no sound evidence to suggest that in ordinary farming practice high herd mortality is positively correlated with high yields. In fact the Cambridge investigation quoted in the report indicated that there was little difference in wastage between high- and low-yielding herds.

Further, when the authors state that there has been over-much propaganda in favour of high yields, it must be remembered that the yield of 3.5 gallons per day, or nearly 1,300 gallons in the year, at which they claim the dairyman obtains highest economic efficiency, is reached by comparatively few cows, while more than half the herds in Great Britain have an average yield of less than half that amount. In practice, therefore,

the choice is not between yields of, say, 1,300-1,500 gallons but probably between yields of 600-800 gallons. It would also be difficult to substantiate the statement that, on the average, milk yields fall by two-thirds following an outbreak of contagious abortion, while it is surely incorrect to measure the trend in yield per cow by two sets of figures so different as the agricultural returns for 1908 and the Oxford Report on Milk Production Costs for 1938.

Part 5 contains the conclusions. Stated briefly, these are as follows. As the State, through its system of social services, accepts responsibility for the education and health of the people, so also should it accept responsibility for their nutrition. A policy of improved nutrition would enable a large increase in the production of health-protective foods, and particularly of milk, to be undertaken by the British farmer. The milk industry would, in fact, form the central feature of the suggested new policy.

The report recommends that the milk industry be removed from producer control, and organized in some form of public utility; that retail prices should be decontrolled, and that steps should be taken to improve methods of production and distribution. The authors also emphasize the need for propaganda to increase consumption, and the continuation and increase of subsidies from the State in order to supply milk to special categories of consumers. They have been impressed by the increasing inability of landlords to supply the industry with long-term credit, and in consequence recommend the formation of regional land improvement commissions empowered to buy agricultural land requiring long-term capital improvement. By this method the State would gradually extend its function as landowner and would be in a position to influence the evolution of agricultural holdings in directions which seemed desirable.

Emphasis is also laid on the need for schemes of livestock and crop improvement, for agricultural research, and for improved social conditions in rural areas. The authors recognize the necessity of subsidizing British agriculture, but they prefer, and rightly, that the principle of comparative advantage should be adopted within the framework of State subsidies, and that public money should be spent on the production of commodities which will most benefit the community as a whole. They also believe that any form of price guarantee should be designed to limit loss rather than to ensure profit.

Although many of their conclusions are likely to prove unpopular with the farming community of Great Britain, the authors are to be congratulated on their courageous handling of a very complex problem.

Advances in Analytical Chemistry

(1) Qualitative Analysis by Spot Tests:

Inorganic and Organic Applications. By Prof. Fritz Feigl. Translated from the latest German edition by Dr. Janet W. Matthews. Pp. ix+400. (Amsterdam: Nordemann Publishing Co.; London: Crosby Lockwood and Son, Ltd., 1937.) 30s.

(2) Mikroanalytische Nachweise anorganischer Ionen:

Ausführung und Reaktionsbilder. Zusammen- gestellt von Gerhard Kramer. Pp. viii+36+8 plates. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1937.) 5.60 gold marks.

(3) The Analytical Chemistry of Tantalum and Niobium:

the Analysis of their Minerals and the Application of Tannin in Gravimetric Analysis. By Dr. W. R. Schoeller. (Published under the auspices of the Society of Public Analysts and Other Analytical Chemists). Pp. xvi+198. (London: Chapman and Hall, Ltd., 1937.) 21s. net.

(4) Quantitative Analysis:

By Prof. W. C. Pierce and Prof. E. L. Haenisch. Pp. xi+412. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1937.) 15s. net.

ALTHOUGH 'spot' methods of analysis are beginning to find their way into text-books, yet Prof. Feigl's treatise is still the standard work on the subject, and by far the most complete exposition of it. Consequently, it is a matter for congratulation that the practical section of the latest (1935) edition (reviewed in *NATURE*, 136, 89; 1935), has been translated into English. The theoretical portion is to be published separately in the future. This English edition is, in some measure, an advance on the original, for it has been brought up to date both by revision and by the inclusion of the most recent work of the author and his collaborators. The majority of these new tests relate to the detection of organic compounds or groups, so that this section now covers a wide field.

Dr. Matthews has succeeded admirably in her role as translator, and one would scarcely have detected that it was a translation but for the use that is made of certain German forms, such as iron (III) chloride instead of our ferric chloride, and that the various publications cited are abbreviated as in the *Chemische Zentralblatt*. The text

contains a number of errors and misprints, some of which have been carried over from the original, while others have been introduced during translation. Fortunately, it is only occasionally that mistakes are found in the actual description of the methods of carrying out the tests, and these are fairly easily detected from the accompanying discussion or from the lists of reagents.

The simplicity of 'spot' tests and the ever-widening range of their usefulness are such as to render this treatise worthy of study by all English-speaking investigators who have anything to do with chemical analysis.

(2) Dealing also with qualitative micro-analysis, this little volume describes tests which are suitable for carrying out with the aid of a microscope. The author has confined himself to the detection of the more common ions, and has chosen reactions that give rise to crystalline forms easily detected or having distinctive colours. He has carefully described the best method of performing these tests in order to secure definite results, but, for this purpose, he has employed pure chemicals and, in many cases, in given concentrations; whether such favourable results are obtainable under the variable conditions to be expected in ordinary analytical work is doubtful.

The tests described by the author are carried out after the usual group separations have been made and, even so, many of them require further separations inside the groups. Thus cadmium is identified either as oxalate or as the double chloride with rubidium chloride: in each case a prior removal of copper is necessary. Similarly, antimony must be separated from arsenic, manganese from zinc, nickel from cobalt and calcium from strontium. The tests are, therefore, mostly confirmatory ones, and are neither so specific nor so elegant as those carried out on filter paper or spotting plates. Nevertheless, there is great scope for the use of the microscope in qualitative analysis, and this monograph, which is well illustrated with many photomicrographs, will serve as a useful introduction to what can be a most fascinating study.

(3) The quantitative separation of tantalum and niobium has been attempted by many chemists during the past hundred years, but it is only recently that Dr. Schoeller and his co-workers have succeeded in achieving acceptable results. The monograph under review describes the methods they have adopted, not only in estimating these elements in the presence of each other, but

also in effecting separations from other metals, particularly those which occur in mineral association with them. The difficulties of the problem have been due partly to the chemical similarity of niobium and tantalum but more particularly to the ease with which their hydroxides, as well as those of certain other earths, can lose their specific behaviour when in admixture, by adopting the properties of the major constituent of that mixture. This phenomenon is attributed by the author to the structural similarity of the hydrated oxides when produced by hydrolytic precipitation, so that the primary sol particles of the colloidal precipitate are heterogeneous, being formed in a manner not unlike that of a mixed crystal.

The volume is well produced and excellently written. The various methods are clearly and concisely described and are illustrated by numerous tables indicating the results obtained by the author in the different separations. There are also interesting chapters on those compounds of tantalum and niobium which are analytically important, on the chemical composition of minerals containing earth-acids and on the use of tannin in other analytical investigations. In addition, there is a section on the qualitative analysis of these metals, and a summary of the original papers on which the text of the monograph is based.

(4) This text-book, although compiled for first-year university students, covers a wide field, while some of the theoretical matter is quite advanced. The work is divided into four sections, the first of which deals with the usual fundamental principles, the use of the balance and the errors and precision of chemical analysis. The second part deals with volumetric analysis, this being treated at some length and in a very comprehensive manner. The different procedures are simply and clearly described, while often there are appended notes which connect theory with practice or emphasize the precautions that must be observed.

The part on gravimetric analysis, introduced by an excellent chapter on the theory of precipitation, contains comparatively few exercises, the intention of the authors being to illustrate the various types of methods rather than to provide schemes for the analysis of many elements. This section concludes with a description of the complete analysis of limestone. Part 4 deals briefly with special methods such as electrodeposition, electrometric titrations, colorimetry and the use of physical methods in analysis. There are the usual tables, while the text is also liberally besprinkled with questions and problems. Like many other American publications, it is excellently printed and attractively bound.

G. R. D.

Exploring in Central Asia

The Silk Road

By Sven Hedin. Translated from the Swedish by F. H. Lyon. Pp. viii+322+31 plates. (London: George Routledge and Sons, Ltd., 1938.) 18s. net.

IN 1935, towards the end of the journey chronicled in this volume, Dr. Sven Hedin marked the fiftieth anniversary of his departure on his first journey in Asia, to the exploration of which he has devoted his whole life. In congratulating him on the unimpaired energy and courage which enabled him to endure the hardships and dangers of Sinkiang in a state of civil war, we add our felicitations on the confidence and respect for his character and achievement shown by the Chinese, notoriously suspicious of foreign men of science, which induced their Government to entrust him with a mission of, to them, signal importance.

The expedition into Sinkiang here recorded started in the autumn of 1933. It was the outcome of certain suggestions made by the author in relation to the position in Sinkiang, the last remaining of the outlying provinces of the Chinese Empire. In consequence, he was invited by the Chinese Government at Nanking to plan and survey

motor roads into the heart of Sinkiang across the Gobi Desert, one of the measures he had suggested to preserve and consolidate the influence of the Chinese Government in the province.

Dr. Hedin's decision as to the most suitable route fell upon the old Imperial road across the Central Asiatic tract, the so-called "Silk Road"—the title apparently is modern, and due to von Richthofen—which had been first traversed more than two thousand years ago, and in its total length of six thousand miles from China to Tyre, had been, as the author puts it, "from a cultural-historical standpoint the most significant connecting link between peoples and continents that has ever existed on earth". By adopting this route it was calculated that a journey to Urumchi, which took a caravan three months, could be accomplished in ten to twelve days.

Of the author's adventurous journeys, this latest was the most dangerous and nerve-racking. The outward journey to Etain-göl was not without its incidents; but although they caused delay, and also anxiety, they were such as might be expected to happen on a journey by car and lorry

in early winter over rough tracks and frozen rivers. When, however, the party crossed into Sinkiang, which, so far as they had been able to ascertain, was reported 'quiet', they found themselves involved in the struggles of two opposing forces, of which one, that of the Mahommedan Tungan leader, was at the point of defeat. They were imprisoned by both forces in turn, and came within even less than the proverbial hair's breadth of being shot. They were detained so long at Urumchi, the turning point of their journey, that an expedition, which had been planned to take eight months, was prolonged to eighteen. The return from Urumchi, including time which was spent in surveying the "Silk Road" and at other

necessary halts on the way, occupied only fifty-three days.

Dr. Hedin describes the outward and return journeys with his customary attention to relevant detail, but his reflections on the general situation, illuminating in their bearing on its development since his book was first published in Sweden in 1936, tend to overshadow the interest of his topography. In view of the Russian economic and political predominance in the province, the author thinks that Sinkiang will be the field of the struggle between Russia and Japan for predominance in the East. China, which has endured for four thousand years without any outstanding military achievement, will, he holds, survive present trials.

An Exposition of Marxism

The Marxist Philosophy and the Sciences

By Prof. J. B. S. Haldane. Pp. 183. (London: George Allen and Unwin, Ltd., 1938.) 5s. net.

PROF. J. B. S. HALDANE is, by his own confession, a recent convert to the philosophy of Marx, and with the characteristic zeal of the convert wishes others to share his faith. If it is necessary or useful for scientific workers to have an explicit philosophy, Marxism is certainly more stimulating than the various brands of positivism that have been popular. It does at least suggest that scientific knowledge is important. Prof. Haldane begins with a brief general sketch of Marxism. He then discusses a number of present-day problems, mathematical, physical, biological and sociological, on this basis. He quotes a number of excellent comments that were made by Engels on the science of his day and are still relevant and illuminating.

As usual, Prof. Haldane displays an astonishing encyclopædic knowledge of science, and is interesting and lucid—except for one point. He does not succeed in dispelling the fog that surrounds the uses of the term 'dialectic'. The mildest use seems only to imply that in any complex system of things, people, or thoughts, opposing forces or tendencies are at work, so that processes are likely to oscillate first one way then another between extremes. The fiercest use seems to mean that Marxist opinion is always right, even if it is wrong, because it is dialectical, and everyone else's always wrong, even if it is right, because it is not dialectical.

Hegel's dialectic, taken as a description of the psychology of thinking in terms of a Heraclitean 'strife of opposites', is not without value. As a

statement of what is logically valid for thought it rests upon a misuse of such terms as 'contradiction' and 'negation' and therefore is confused, if not entirely wrong. Hegel tried to display the universe as a product of thought and this was, as many suppose, a fatal error. Marx tried to correct the error by inverting the Hegelian method. He treated thought as a product of human activity within a universe that is in itself other than thought. This may be an improvement: but he took over the Hegelian dialectic, inverted but retaining its inherent confusions. Heraclitus, who lived before logic had been invented, may be pardoned for stating his doctrine of 'the strife of opposites' without regard for logical rules, but his modern followers ought not to claim so much licence. In particular, the advocates of dialectic ought not to use the logical fact that every proposition has one contradictory and one only, to infer that in any situation there can be only two opposed tendencies or processes, whereas there may be many. The doctrine that the course of human history can be predicted rests on this assumption, and might be true if it were valid. In some instances the assumption may be harmless, but it is at best an over-simplification and a hindrance to clear thinking. Another source of difficulty is the notion that double negation has some mysterious virtue unknown to strict logic.

This is perhaps less a review of Prof. Haldane's book than an attack on dialectic. But while its dialectical confusions remain, the Marxist philosophy can scarcely be as helpful to scientific workers, or anyone, as the author would wish it to be. Possibly he is the man to put them right.

A. D. R.

A Catalogue of the Ammonites of the Liassic Family Liparoceratidae in the British Museum (Natural History)

By Dr. L. F. Spath. Pp. ix + 192 + 26 plates. (London: British Museum (Natural History), 1938.) 30s.

THIS work has a much wider significance than might be inferred from the fact that it deals with only one family of ammonites, and that a comparatively short-lived one. Unlike most writers on ammonites, the author attaches but little importance to phylogeny which is based on the evidence of ontogeny. Previous work on the family Liparoceratidae has been done by Hyatt, Buckman, and Trueman, and their conclusions rest mainly on the assumption that the phylogeny of an ammonite may be seen in its ontogeny. According to these authors, the evolute capricorn Liparoceratids were ancestral and gave rise, through the dimorphs, to the involute spherocoones.

In the view now put forward by Spath this order of evolution is entirely reversed. He maintains that the more or less involute (closely coiled), often spherocoone, Liparoceratids are ancestral to the more evolute (dimorph) forms, and that these in turn gave rise to the capricorns, which are the most evolute Liparoceratids. This order of evolution is borne out by the stratigraphical succession which, owing largely to the work of Dr. W. D. Lang, is now known in much greater detail than hitherto, and shows that there are no capricorns among the early Liparoceratids.

In his systematic and phylogenetic work, Spath relies mainly on resemblances in the characters of the adolescent and adult stages, on the existence of passage forms, and particularly on the order of appearance in time of different ammonites. He considers that the value of small differences in the suture line has been greatly over-rated; that the position of the siphuncle in the early stages of development is too variable to be of importance; and that too much stress has been laid on the configuration of the earliest whorls. He shows that new characters often appeared in the younger stages of development, and, as evolution proceeded, spread to later whorls.

The numerous and excellent illustrations will enable readers to follow in some detail the author's views on the evolution of the Liparoceratidae, and the glossary of technical terms will be of value to those who have not made a special study of this group of fossils.

Fernsehen:

die neuere Entwicklung insbesondere der deutschen Fernsehtechnik. Vorträge von M. von Ardenne, Dr. F. Banneitz, Dr. E. Brüche, W. Buschbeck, Prof. Dr. A. Karolus, Dr. M. Knoll, Dr. R. Möller, Prof. Dr. F. Schröter. Herausgegeben von Prof. Dr. Fritz Schröter. Pp. vi + 260. (Berlin: Julius Springer, 1937.) 21 gold marks.

IN the autumn of 1936 the German Society of Electrical Engineers (Elektrotechnischer Verein) and the German Post Office arranged a course of lectures on

television at the Technische Hochschule, Berlin. These lectures were intended to give to a technical audience an introductory survey.

The present book is based on this course and contains the contributions of the various lecturers (most of them well-known specialists in their subjects) in abstracted form. The book covers the ground very well. It deals not only with the electron optical systems of television, but devotes also adequate space to the mechanical systems. It pays special attention to the problem of transmitting television signals by radio or by cable and also contains a chapter on large-screen television.

The treatment of the subject by the various contributors is as a rule clear, though naturally concise; and the essential points are well brought out. The only notable exception is the discussion of the optical efficiency of mechanical scanners, where some vague statements are made.

The book is a valuable addition to the few existing text-books on the subject, though its main use to English workers will be as an account of German tendencies and the state of development reached by the end of 1936.

The Principles of Soil Science

By Prof. Alexius A. J. de Sigmond. Translated from the Hungarian by Prof. Arthur B. Yolland; translation edited by G. V. Jacks. Pp. xiv + 362 + 4 plates. (London: Thomas Murby and Co., 1938.) 22s. 6d. net.

PROF. DE SIGMOND'S "Általános Talajtan" has been translated into English and adapted by omitting the sections on soil physics and microbiology from the agronomy section, and other material of only local interest.

Part 1 deals with soil genetics. The chemical composition of rock-forming minerals is not given, the author stressing the point that it is the chemically weathered part that is of particular significance in soil formation and the development of soil character. The relative influence of soil-forming factors is fully discussed and the effect of climate on soil development well portrayed. In the agronomy section the chemical properties of soils are described and their method of presentation leads logically to the system of classification adopted.

The main section of the book—soil systematics—is treated from a novel aspect, as the classification is based on the results of leaching experiments. It is fully comprehensive, is based on the characteristics of the soil and in addition is claimed to depict the genetic and dynamic character of the soil. Twenty-five soil orders are described and each is subdivided into main types of which the eight in soil order XI largely cover the range of useful soils.

Part 4—cartography—contains useful suggestions for the mapping of small areas and the dissemination of useful advice to farmers in the form of practical soil maps showing one variant each, for example, need for lime, pH values, manurial requirements, etc. Four well-produced plates are included in an appendix to this section.

J. W. B.

Physics and the Physicists of the Eighteen Seventies*

By Sir Ambrose Fleming, F.R.S.

IN 1874 the Physical Society of London was founded by a well-known physicist, Prof. Frederick Guthrie. The first meeting of the Society was held on March 21, 1874, in Guthrie's lecture room in the Science Schools, South Kensington, and by his great kindness I had the privilege of reading the first paper to the members, the subject being "The New Contact Theory of the Galvanic Cell".

Let us then take a glance backward at the state of physics in the years 1870-1880, and the men who were foremost in advancing it. We may divide them into two broad classes. There were first a few who were highly competent mathematicians and conformed to the model of Newton in being able not only to wield the powerful weapon of mathematical analysis but also were competent experimentalists. In Great Britain at that time this class was chiefly represented by Sir George Stokes, Lucasian professor of mathematics in the University of Cambridge, by Sir William Thomson, who had held the chair of natural philosophy in the University of Glasgow since the time when he was twenty-two years of age, and by his enormous knowledge, brilliant experimental researches and practical inventions held a foremost place in universal opinion as a physicist. Then next by James Clerk Maxwell, who, even as an undergraduate, had made notable contributions to mathematics and physics. He had translated Faraday's physical conceptions into mathematical language, explored the phenomena of colour, laid firm the foundations of the kinetic theory of gases and made important measurements of the viscosity of air. He had held professorships of natural philosophy at Aberdeen and King's College, London. In 1865 he had resigned this latter appointment and retired to his Scottish estate at Glenlair to engage in writing his great treatise on "Electricity and Magnetism".

Peter Guthrie Tait was then professor of physics in the University of Edinburgh. As a mathematician he had inherited the mantle of Sir W. R. Hamilton, the inventor of quaternions, but Tait also made many very important contributions to experimental physics. Then in the same rank of great mathematical physicists, we had in Germany Helmholtz and Kirchhoff; in France, Cornu, and in the United States, Willard Gibbs. On the other hand, there were many eminent physicists who,

like Faraday, had not much mathematical knowledge, but attained their results purely by experimental work. Among these in the eighteen seventies, John Tyndall was one of the most popular. He had very great abilities as an exponent of science. J. P. Joule had made the most valuable contributions to physical measurements by his proof of the so-called Joule's law in electricity and in his determinations of the mechanical equivalent of heat. A reprint of Joule's scientific papers was issued by the Physical Society in 1884.

Very prominent in this group was William Crookes. He had, like many of the experimental physicists, begun as a chemist. Crookes discovered by spectrum analysis the element thallium, and had isolated the metal and determined its atomic weight. Crookes had then turned to research on electrical discharge in high vacua. He had improved methods of vacuum technique and had rediscovered many important facts concerning electric discharge in high vacua noticed by Hittorf, Pöluj and others. Finally he devised the light-mill or radiometer.

Another of this group was J. H. Gladstone, the first president of the Physical Society, and he also was first of all a chemist and latterly an experimental physicist. His work on refractive indices was of special importance. Neither must we omit to mention in this group the name of Frederick Guthrie, who made several very important additions to physical knowledge. Other experimental physicists of that date were R. B. Clifton at Oxford, W. Grylls Adams and G. Carey Foster in London, Balfour Stewart in Manchester. Prior to about 1866, there were in Great Britain scarcely any laboratories properly equipped for research or teaching in physics.

The necessity for quantitative work, especially in electricity, had been emphasized by the technical advances in telegraphy. In 1856, a far-seeing man, Cyrus Field, had conceived the idea of a trans-Atlantic submarine cable to unite Great Britain and the United States, and had formed a company in 1856 to undertake it. But the question at once presented itself whether signals could be sent through such a long cable quickly enough to enable a sufficient income to be earned to pay the interest on capital and also the working expenses. Faraday had been consulted, and pointed out that such a submarine cable was a large condenser or Leyden jar, but he thought signals might be sent through it sufficiently quickly to make it pay..

* From an address delivered before the Physical Society on January 12.

Here we see the immense power of mathematical analysis guided by correct physical ideas. In 1855 William Thomson, then a young professor, sent a paper on the theory of the electric telegraph to the Royal Society. Assuming the cable to have certain resistance and also electrostatic capacity per mile, he proved that when a steady electromotive force was applied at one end the outgoing current at the other rose up gradually according to a certain curve of arrival. The time taken to reach a certain current strength was directly proportional to the square of the length of the cable and directly as the product of the resistance and capacity per mile of the cable. This showed that the right method for signalling was to have as sensitive a detector as possible at the receiving end and to use the lowest possible applied electromotive force at the sending end. Thomson had meanwhile invented and made his sensitive mirror galvanometer for cable signalling.

By 1865, three Atlantic cables had been laid and lost. But in 1866 success finally crowned the efforts of the promoters and a fourth cable was made and laid and the 1865 cable raised and repaired. Thus two complete Atlantic cables effected communication between England and the United States, which were worked with Thomson's instruments. In 1870, Thomson invented his remarkable syphon recorder to receive and print cable messages, and this has remained to this day the standard instrument for all cable reception.

Thus the year 1870 saw the practical achievement of submarine telegraphy accomplished and the invention of the instruments needed for working. From that time the making and laying of submarine cables became a particularly British industry.

But the same year (1870) witnessed another event of great importance with regard to physical research, namely, the founding of the Cavendish Laboratory at Cambridge. Although some attempts had been made to foster physical research there, the University was without means to provide for it. In October 1870, the seventh Duke of Devonshire, then Chancellor of the University of Cambridge, sent a letter to the Vice-Chancellor offering to defray the cost of erecting and equipping a physical laboratory in the University. This munificent offer was gratefully accepted. In March 1871, Maxwell was elected as the first Cavendish professor of physics. The building of the Laboratory was completed early in 1874. A year before, in 1873, Maxwell had published his great treatise on "Electricity and Magnetism", and physicists everywhere were trying to master the new ideas he had introduced into the subject. He had embodied in it his earlier work of expressing in mathematical language Faraday's ideas of lines of electric and magnetic force and of the dielectric

as the true seat of the energy involved. He had also included in the second volume a reproduction and exposition of his great paper sent to the Royal Society in 1864 on "A Dynamical Theory of the Electromagnetic Field". In this paper he had shown that electric and magnetic effects are propagated through space with a velocity equal to that of light in the medium and had foretold the existence of the electromagnetic waves now utilized to give us radio-telegraphy and telephony.

After Maxwell's death in 1879, I remember that an eminent mathematician, Sir W. D. Niven, said to me that he regarded this paper with its wonderful originality and power to be one of the greatest productions of the human mind.

In his introductory lecture given by Maxwell in October 1871 on his installation as Cavendish professor, he had expressed his ideas of the aim and functions of the Laboratory. He did not contemplate its main use to be that of training undergraduate students in the repetition of experiments described in text-books, but that its principal object should be quantitative measurements and the production of new knowledge by research by post-graduate or other students. Very magnificently has this ideal been held in view by Maxwell's successors in the chair.

Another event in the year 1870 which had an influence on physical research was the taking over by the State of the telegraph system in Great Britain. Up to that time, land telegraphy had been conducted by several public companies each with its special area of operations. This of course greatly limited the use of the electric telegraph.

The Government of that day passed Acts of Parliament in 1868 and 1869 entitling it to buy out, take over, and place under the General Post Office all telegraphic work in Great Britain. At the same time, it was greatly extended and the country overlaid with a network of telegraphic wires enabling communications to be made between all places where there was a post office. This called for the production of practical standards of the electrical units such as the ohm, the volt, the ampere, the farad, and accurate methods of electrical measurement. A British Association Committee had constructed a number of coils of wire of various alloys the resistance of each of which was asserted to be at certain marked temperatures equal to 10° absolute units of resistance on the electromagnetic system. These had been deposited in the Cavendish Laboratory.

When I went up to Cambridge in October 1877 to work in the Cavendish Laboratory, Maxwell suggested to me to undertake the work of comparing these coils and ascertaining from them their resistances at certain temperatures and hence the most probable value of the B.A. Unit.

For this purpose I devised a special form of Wheatstone's bridge which was described to the Physical Society in 1880. I prepared, as the result of about two years work, a chart showing the variation of resistance with temperature of each of the coils. The true absolute values of these were determined later on (after Maxwell's early lamented death in November 1879) by Lord Rayleigh, who was Cavendish professor until 1884. This B.A. Unit proved to have an electrical resistance of 0.9887×10^9 centimetres per second or less than a true ohm of 10^9 cm./sec.

Part of Maxwell's work during the last years of his life comprised the editing for publication of the unpublished electrical researches of the Hon. Henry Cavendish (1731-1810). Cavendish was an experimentalist of great ingenuity, and with the most rudimentary apparatus carried out important researches. Maxwell repeated with similar apparatus all Cavendish's results. Among other things, Cavendish anticipated Faraday's discovery of specific inductive capacity and made researches to find out if the law of electrical attractions or repulsions varies in any sensible degree from the inverse square of the distance. Maxwell carefully repeated these with improved apparatus and found that the index deviated from 2 by not more than $\frac{1}{1000}$ either way. Cavendish made measurements of the comparative electrical resistance of various materials by taking the shock of a Leyden jar through a certain length of each material and adjusting the lengths until the shocks were estimated to be about equally painful. Most of the workers in the laboratory were called upon at various times to act as 'shock meters' in Maxwell's repetition of Cavendish's experiments.

Maxwell's lecture experiments were always marked by great ingenuity, and he could give copious new information on even the most familiar scientific facts or discoveries. In conversation he was often difficult to understand by reason of a certain paradoxical and humorous mode of speech.

No mention of Maxwell's work would be complete without a brief reference to his other writings, written in the eighteen seventies. He published a treatise on the "Theory of Heat" which had all the characteristics of lucidity and novelty which marked his authorship. In it he gave the elements of the science of thermodynamics and the contributions to it made by Carnot, Clausius, Willard Gibbs, Rankine and W. Thomson. His other small book "Matter and Motion" was a delightfully interesting small treatise on dynamics. It was re-edited with some additions after Maxwell's death by Sir Joseph Larmor. In addition to this he wrote many articles for the ninth edition of the "Encyclopædia Britannica", and in 1878 gave a memorable lecture on "Molecules" to the British

Association at Bradford, parts of which have been often quoted.

We must now return to consider the work of Sir W. Thomson (later Lord Kelvin) during the decade 1870-80 under consideration. He was at this time engaged in improving the mariner's compass. As a yachtsman and the owner of the *Lalla Rookh*, he took an extreme interest in all things connected with navigation, and left his improvements on everything. In 1874, he was asked to write an article on the magnetic compass for *Good Words* and at once took note of the defects of the then used type. Little by little he brought it to a state of perfection in which it was adopted all over the world. He gives a full account of it in the third volume of his popular "Lectures and Addresses". At the same time he vastly improved the method of deep-sea sounding by using steel pianoforte wire instead of hemp rope. The depth was measured by the degree to which the air in a glass tube open at the bottom but closed at the top was compressed when the sea floor was reached. In 1876 he made known his enormously ingenious machines for recording, analysing, and predicting the tides at any port, and in a lecture at Glasgow in 1875 he gave a most instructive account of methods of determining the position of a ship at sea by Sumner circles. His knowledge of everything connected with navigation, tides and waves was vast and accurate, and he touched nothing he did not elucidate and improve.

The decade we are considering was remarkable also for the completed invention of two important electrical appliances, namely, the speaking telephone and the incandescent electric lamp, the achievement of which had long been objects of physical research.

Without reference to early attempts, it is well known that Alexander Graham Bell was the first to produce a simple speaking telephone which was publicly exhibited in 1876 at the Philadelphia Exhibition. Sir W. Thomson saw and used it there and on return to England described it enthusiastically to an audience at the British Association meeting at Glasgow. Bell was actually engaged in trying to effect multiple telegraphy when he stumbled across the principle of his magneto-telephone.

The Bell telephone was a good receiver but poor transmitter. T. A. Edison had meanwhile invented his carbon button transmitter, in which the motions of a sound-actuated diaphragm compressed a button of lamp-black and varied its resistance and therefore the current in the circuit. D. E. Hughes, the inventor of a printing telegraph, then came into the field in 1878 with his discovery of the effects of slight pressure on a loose contact between two pieces of graphitic-carbon. This in time gave

us the modern microphone transmitter. Bell had suggested meanwhile the idea of a telephone exchange, and the Edison and Bell interests in England had to unite to provide the most effective transmitter and receiver.

The problem of incandescent electric lighting had occupied attention for thirty years or more in the endeavour to provide a small unit of light for domestic illumination. J. W. Swan solved the problem early in 1880 of producing a carbon filament by carbonizing a cotton thread which had been parchmented by sulphuric acid and mounting a loop of this carbon filament in a glass bulb exhausted of its air. Edison about the same time carbonized slender filaments of bamboo in horse-shoe shape and also produced an effective carbon filament lamp.

The early lamps gave a light of about sixteen candles at a power expenditure of about sixty-four watts. From that date electric illumination by incandescent lamps became practicable.

In conclusion, it may be useful to attempt to sum up briefly the achievements in physics during the decade 1870-1880. Broadly speaking, it was an age of practical invention in which well-ascertained scientific principles were applied in some way to create new industries or useful arts. In telegraphy there were many very important additions. Wheatstone automatic, quadruplex and high-speed printing telegraphs came into use. The speaking telephone and telephone exchanges added to the convenience of life. Electric incandescent lamps and the invention of the dynamo had made possible public electric supply stations and domestic electric illumination.

In 1873 the reversibility of the dynamo was discovered; that is, that it could act as a motor when current was put into it, and some degree of progress had been made in the use of electric motors and possible electric transmission of power.

In relation to physical theories, the period we are considering was essentially mechanistic and deterministic in ideas. The conception of a universal ether having elasticity and density was widely held and numerous mechanical ether theories proposed. Atoms in vibration were supposed to agitate the ether and produce waves in it, but no one had explained how the vibrating atoms got a grip on the ether seeing that the ether offers no resistance to the motion of the earth and planets through it.

Theories of atomic structure were in a very vague and nebulous state. Thomson's theory of atoms as vortex rings in the ether had not explained anything of importance. The science of thermodynamics had, however, been well developed and much progress made by the writings of Clausius, Rankine, W. Thomson and Willard

Gibbs. The foundation stone of the science of thermodynamics was laid by the publication in 1824 of the remarkable essay by Sadi Carnot on the "Motive Power of Heat" in which he gave the Carnot cycle. This essay was, however, then known to very few. W. Thomson made acquaintance with it when as a young graduate he went for a year to Paris to work with the great experimentalist, Regnault. Thomson published in 1849 a paper in which he made known and expounded Carnot's work. Carnot's essay in French was republished in 1878, having been thus lost sight of for many years, but Thomson's paper in 1849 had by that time brought it to the notice of physicists of that day. Based on the Carnot cycle, Thomson afterwards suggested his absolute scale of temperature independent of any working substance. He also enunciated his Law of Dissipation of Energy. The fact that heat is the kinetic energy of atoms was fully understood and that the whole of any amount of mass kinetic energy could be converted into heat at a certain rate fully appreciated. But it was not so generally realized that the whole of any quantity of heat energy cannot be converted into mass kinetic energy. There was a widely diffused belief in that day that the physical theories corresponded closely to reality and that such words as size, time, mass and energy denoted actualities independent of any observer. Not every physicist, however, shared this view. Maxwell once said in my hearing, "Because we can imagine a mechanism which can achieve some result we find in Nature, it does not in the least follow that it is done in that way."

The physical theories of 1870-1880 were looked upon as well-established explanations of facts. Not ten years later, however, the first of the events occurred, namely, the Michelson and Morley experiment, which was to undermine and destroy this confidence and show that our interpretation of physical phenomena involves the observer as well as the thing observed.

When we come to look back then on the work of physicists during the eighteen seventies, what we find is that their inventions, discoveries of fact, and ascertained principles remain with us to-day of permanent value, forming part of our useful knowledge. But their theories and speculations as to underlying causes and nature have nearly all passed away. Perhaps it will also be the same with our present-day work. If some sixty years hence a fellow of the Physical Society gives a talk on the physics of the nineteen thirties, he will have to record the great additions then made to knowledge of physical facts. But he may also have to say that our explanations and theories concerning them have all vanished, or at least been replaced by others also destined in turn to pass away.

Progressive Education

The Spens Report*

THE publication of what has already become known as the Spens Report is of great significance for the educational system in England and Wales, and its complete or even partial adoption will be of far-reaching importance.

The Consultative Committee responsible for the Report, under the chairmanship of Sir Will Spens, master of Corpus Christi College, Cambridge, was a strong one. Its terms of reference were to examine the organization and so forth of schools other than those administered under the Elementary Code which provide education for students beyond eleven plus years, "regard being had in particular to the framework and content of the education of pupils who do not remain at school beyond the age of about 16". In view of the potent criticism aimed at present-day secondary school education in that, as the Report points out, it generally seeks to satisfy the curricula inspired by the various school certificate examinations, the latter part of the Committee's aim is well timed and of the utmost importance, because it is only a small percentage of secondary school students who eventually proceed to the universities.

To-day, the Board of Education recognizes nearly one thousand four hundred secondary schools, and these contain altogether nearly half a million students. That is, nearly 12 per cent of the child population of secondary school age in the country receive a secondary school education.

The Committee adopted a liberal point of view by considering education "in terms of activity and experience rather than of knowledge to be acquired and facts stored". It was appointed in March 1935 and since that date has examined one hundred and fifty witnesses, while various sub-committees have examined twenty-two witnesses. These witnesses can be taken as widely representing educational thought since they have been drawn from the Board of Education, directors of education and members of local education authorities, associations representing those officials, organizations representing teachers, other organizations, and many individuals including school inspectors, professors of education, psychology and physiology, and head masters and head mistresses of public, secondary, technical and senior schools.

* Report of the Consultative Committee on Secondary Education with Special Reference to Grammar Schools and Technical High Schools. Pp. xxviii+475. (London: H.M. Stationery Office, 1939.) 3s. 6d. net.

GENERAL RECOMMENDATIONS

One of the outstanding features of the Report is the revolutionary changes suggested in secondary school organization and classification, to be outlined in the next section. This is doubtless due to the realization that the aim of secondary education is now not to train children "to work with their heads rather than with their hands", for conditions have now changed: democracy is challenged and "the duty of citizenship in a democracy renders it essential that all should be taught to understand and to think to the best of their ability". Those children who are capable of thinking best in abstract terms would undoubtedly derive greatest benefit from the academic training of the Grammar and Technical High School. But it is equally as important that many children, some of them of marked ability, would profit best by a Modern School education. This being so, careful allocation of children at eleven plus years from the primary schools to these schools is a matter for serious consideration.

In view of this, the Committee directs attention to the unfortunate fact that Grammar and Modern Schools are at present administered under different codes and often by different authorities. Differentiation goes even further in the scales of teachers' salaries, types of buildings, quality of equipment, size of classes and so forth. To eliminate this, it is suggested that all secondary schools—Grammar, Modern and Technical High Schools—should be placed on an equal footing so far as these conditions are concerned. The maximum size of classes should be thirty, and (with special permission of the Board of Education) should never exceed thirty-five. It is suggested, too, that all fees should eventually be abolished as soon as the financial condition of the State renders this possible.

SCHOOLS AND THEIR CURRICULA

A revolutionary change in the organization of schools offering a secondary education is visualized in the Report. It should be possible for children of eleven plus years to be transferred to one of three types of secondary school, namely, the Grammar School, the Technical High School or the Modern School (at present known as the Senior School—a term used by the Board of

Education to designate both selective and non-selective Central Schools). Transfer between these schools should be possible at thirteen plus years, but attendance should be compulsory at one or the other of them up to sixteen years. Transfer at thirteen plus years should also be possible to technical schools, which include Trade, Junior Technical, Home Management and Junior Commercial Schools: but here also, attendance up to sixteen years should be compulsory. In all types of schools, education should be brought into closer contact with the practical affairs of life, and the first two years of all schools should have a common curriculum.

Education in the Grammar School should be suitable for students passing on to the universities: but reconsideration of the curriculum in these schools is now essential. There is, at present, a grave tendency to over-work and over-strain the adolescent students, especially in girls' schools.

The curriculum in Grammar Schools should allow for the teaching of all subjects allowed at present, so far as this is possible. Proposals have already been made for a greater unification of the subjects, but these should be treated with the utmost caution. It is not certain, for example, that geography, if combined with history, could retain the distinctive character which it has achieved in the hands of modern scholars. Yet, there is much to be said for the intimate alliance between subjects, provided the essential autonomy of each is preserved. The teaching of physics and mathematics, for example, suffers much from a separation which Newton would have found incomprehensible. Subjects are also needlessly subdivided—a subdivision which in some cases, for example, mathematics (the separation of plane from solid geometry, of elementary calculus from algebra), physics and biology (for example, neglect of zoology compared with botany), tends to distort rather than bring out the characteristic architecture of the subject.

The curiosity of children of secondary school age about the practical concerns and activities of the world is frequently so strong as to amount to a passion. Advantage should be taken of this in order to bring the studies of the secondary school into closer contact than at present with the practical affairs of life. In mathematics, physics and chemistry, for example, the 'problem method' should be the standard mode of procedure—practical questions of wide interest and utility being made the occasion for the introduction of new mathematical or scientific knowledge and technique. If the utility phases were adequately developed in all subjects, everything which those concerned about 'education for citizenship' rightly demand would probably be granted.

Important defects in the teaching of mathematics are emphasized in the Report. This is ascribed to an imperfect synthesis between the idea that some parts of mathematics are useful to the ordinary citizen or to certain widely followed vocations and should therefore be taught to everybody, and the old idea that when mathematics is not directly useful it has indirect utility in strengthening the process of reasoning and in inducing a general accuracy of mind. It is suggested that mathematics can be put on a sound footing only when it is taught as other subjects should be taught, since it is one of the main lines which the creative spirit of man has followed in its development.

The approach to science, too, needs readjustment. It should not be by way of a systematic study of particular sciences, as is the method adopted in most schools. This feeling has already led, in some schools, to the provision of courses in general science as an alternative to courses in particular sciences. This general science tends to relate science to everyday experiences. It avoids what is of a purely academic nature and illustrates laws and general principles by special reference to practical applications drawn from the physical and biological worlds. In this way, general science makes more direct contact with life and creates real interests.

The teaching of science has lost close touch with life itself, and for this reason has often failed either to give the knowledge required or to stimulate the student's interest. The Committee believes that there is a general body of knowledge, not confined to either the physical or biological sciences as they are generally considered, which ought to be known by the average citizen. In boys' schools especially, science is too often restricted to the physical subjects. It is now suggested that in science teaching the pupils should be given some knowledge of the natural laws which operate in the universe. It should reveal the influence of scientific thought and achievement on the evolution of our present-day civilization, and it should show the possibilities (for good and for evil alike) in the future of the human race. The appeal here is to social interest and social utility.

Therefore, in physical sciences should be included astronomy (since the earth is only a very small portion of the whole), physics, chemistry and possibly some geology. Some astronomy is considered to be essential. In chemistry, a certain amount of organic studies, such as fermentation and saponification, should find a place, as they do in most American schools. The approach to biology should be through natural history, with primary emphasis on plants. This should merge later into the general characteristics of living organisms, taking examples from plants, and animals, including man.

In country Grammar Schools full advantage should be taken of the rural environment. Though the reforms suggested for the urban Grammar Schools apply also to rural Grammar Schools, it must be realized that the latter have special difficulties and special advantages. The resources of the countryside are at the disposal of the teacher. Rural schools enjoy unrivalled opportunities for framing syllabuses which have a high practical value derived from their close affinity to the world outside the school, and at the same time should develop in the student an inquiring and critical mind and the power of independent judgment.

Among the features prominent in the curriculum of a rural Grammar School should be the local survey and the school garden. A general local survey could be the basis of much geography and history teaching. The school garden, apart from its intrinsic merits as a means of teaching biology and agriculture, could be an agent in agricultural research such as the testing of new fertilizers. Sir John Russell stated that this has already been done in certain schools in connexion with the Rothamsted Experimental Station, and the pupils realized that they were being employed in a joint enterprise by a great scientific institution and that this was not an exercise book problem but "something which mattered". Bee-keeping and poultry husbandry should be encouraged in the rural schools. Elementary mathematics should be based on the farm and the local survey; material and statistics should be taken from them. Science should have a biological bias, and domestic science should include training in the utilization and conservation of farm and garden produce.

The technical schools of the Report include Trade Schools, Junior Technical Schools, Home Management and Junior Commercial Schools. These have developed their curricula on a broad scientific, utilitarian and vocational basis, and thus offer appropriate courses for a certain type of pupil. In this they are justified, but the Committee does not consider that they offer a real alternative to the Grammar School, and therefore it has suggested the institution of a new type of school, namely, the Technical High School.

The Technical High School should provide good intellectual discipline apart from the more purely technical training. Therefore, during the first two years, teaching should be of a general secondary school type. In other words, this school should develop a curriculum designed to provide a liberal education, with science and its applications as the core of inspiration. The subject material should include English, history, geography, mathematics, science, engineering drawing, handicrafts, physical education, aesthetic subjects, and a foreign language (preferably German) where the

student shows special capability of profiting by it. The method of teaching science in the Technical High School will clearly be different from that adopted in the Grammar School. The Technical High School should also offer a new type of leaving certificate having the same status as the first school examination, that is, fulfilling first conditions for matriculation.

FIRST SCHOOL CERTIFICATE EXAMINATION

The present first school certificate examination is subjected to severe criticism in the Report. It is remarked that the examination should follow the curriculum, not determine it. Profound changes in the syllabus are recommended, and it is suggested that greater use be made of school records.

In its present form, the school certificate tends to enforce uniformity in the curriculum. This is probably due to the fact that it is used as a test of education received and as a means of exemption for matriculation into the universities. It should not be used as a substitute for the matriculation examination, but should be a conditional first step towards the latter.

Greater freedom of choice of subjects should be allowed. There should be a reduction in content of the syllabus, and a candidate should be required to pass in at least five subjects, including English and either a foreign language or science (including mathematics). Thus, no candidate would be prevented from obtaining a certificate solely by reason of lack of linguistic or mathematical or scientific ability. The recommended reduction in content of the mathematics course and a simpler course in science would involve greater variation and some lightening of the syllabus; but no lowering of the standard of marking is implied.

Post-certificate work in the sixth form, possibly leading to the higher school certificate examination, should be encouraged for the benefit of students about to enter the universities.

PHYSICAL AND PSYCHOLOGICAL PROBLEMS

Physical and psychological problems receive due consideration in the Report. For example, physical training and physical fatigue and strain are of paramount importance in any school, and to ignore them would necessarily involve serious consequences. The physical growth of the child at puberty and adolescence must be considered in relation to such problems as posture, self-control, etc.

No adolescent, until calcification of the bones is complete, should be allowed to do heavy continuous

muscular work, either in or out of school, particularly if it involves postural fatigue. Risks of spinal curvature must be avoided, and the importance of adequate rest in a suitable position should receive careful consideration.

The onset of puberty must be recognized by the authorities through the characteristic well-marked physical and mental changes, and due allowances made for it. During this period, especially in girls, ample provision should be made for a liberal dietary and well-balanced periods of exercise, rest and sleep.

It is a matter for regret that some authorities do not provide for medical inspection and treatment in Grammar Schools. The practice of medical inspection and treatment should be made universal, and medical officers should be encouraged to undertake a wider scope of inquiry. Meals should be available at all schools, and in arranging

the dietary, the school medical staff should be consulted.

The psychological factors influencing the pupil in his mental development and his education should be studied continuously by the school teaching and school medical staff. These include the general characteristics of puberty and adolescence, mental and intellectual abilities, individual differences and special intellectual capacities, sensory capacities, attention, memory, imagery, reasoning, emotion, social impulses, self-assertion and submission, and so forth. In fact, the application of psychology to the study of the school child is of a special character, and therefore cannot be ignored. All trained teachers have received special instruction in this aspect of their careers, and this should make these problems less formidable than they would otherwise be, but it does not detract from their importance.

The Weather in Great Britain during 1938

By E. G. Bilham

SIR NAPIER SHAW, in the delightful Christmas card which his friends have been privileged to receive, describes the year 1938 as *annus memorabilis*. The description is a happy one, for the year was memorable in many respects. The amount of material available at the moment for the purpose of summing up the features of the year as a whole is relatively small, and we cannot here attempt anything in the nature of a detailed discussion. It has been thought, however, that a retrospect of the more striking meteorological events would be of interest.

The year began with a mild, wet and stormy January. In many parts of England and Wales no temperature below 32° F. was recorded, and in most districts the mean for the month was about three degrees above normal. Gales were numerous, and that on January 14-16 was exceptionally severe. A gust of 101 miles per hour was recorded at St. Ann's Head on January 15. A similar velocity was reached at the Liverpool Observatory on January 29, and 100 miles per hour was also recorded in the Orkneys on January 23. A magnificent display of the aurora occurred on the night of January 25-26.

Conditions in respect to warmth and wind were less abnormal in February, but it produced one of those coincidences of tidal and meteorological conditions necessary for the occurrence of floods on the east coast of England. Such flooding occurs when a wind-induced deepening of the waters of the North

Sea, due to strong winds from the north-west quadrant, coincides with a high-predicted tidal level. These conditions prevailed on the evening of February 12, when the sea burst over the low-lying coastland between Winterton and Palling in Norfolk and flooded an area of the order of fifteen square miles. Later, on April 3, the sea broke through the defences at Horsey and caused a further extensive inundation. The rainfall of February was very deficient except in parts of Scotland, the general fall over England and Wales being about half the normal.

The shortage of rainfall south of the Border was accentuated in March, when the general fall for England and Wales was only 27 per cent of the normal. It was the driest month of that name at many stations. On the other hand, parts of Scotland had excessive rainfall, as much as 50 inches being recorded at Loan (Loch Quoich). The month will also be remembered for its remarkable warmth. Previous records of mean temperature were exceeded by a substantial margin. For example, at the Radcliffe Observatory, Oxford, where records on a comparable basis are available back to 1815, March 1938 gave a mean value exceeding the previous highest (1822, 47.3° F.) by as much as 2.6° F.

April continued the sequence of dry months. For the British Isles as a whole, it was the driest April on record, and probably the driest month of any name. The total rainfall of the three months

February to April 1938 was less than that of any similar period back to 1785. Some rural districts experienced an acute shortage of water. Severe frosts during the periods April 9-11 and again about April 18-19 caused much damage to the blossom and buds of fruit crops.

There were further damaging frosts in the early days of May, the reading of the screened minimum thermometer being as low as 18° F. on May 8 at Thetford, Norfolk. A week later a temperature as high as 79° F. was registered at Norwich and Canterbury. June was rendered noteworthy by the great gale on June 1-2, during which the gusts recorded on the south coast were comparable with those of severe winter storms. This storm produced a remarkable discoloration of foliage of trees in the south of England, due probably to the combined effects of buffeting and salt spray borne inland by the wind.

July was a wet month, with a very marked deficiency of sunshine. A very heavy rainfall occurred in the English Lake District on July 29; the reading amounted to 5.95 in. at Watendlath Farm and to 5.60 in. at Borrowdale.

The first day of August was the warmest of the year, 87° F. being recorded in London on that day. Thunderstorms were frequent and severe during August. During one of these the remarkable rainfall of 6.39 in. occurred at Torquay on Aug. 4.

The early autumn was relatively uneventful, but November was remarkable for exceptional warmth in all districts. On November 5, 70° F. was registered in many parts of east and south-east England. The mean temperature of the month, 49.3° F., was the highest in November at Oxford since 1818. A very severe gale occurred on November 23, the gust velocity reaching 108 miles per hour at St. Ann's Head; 98 miles per hour was registered at Stornoway on November 18.

The abnormal warmth was maintained during the first half of December. There was an abrupt change on December 17, when Great Britain began to be affected by very cold air spreading eastward from the continent of Europe. The wintry conditions lasted over the Christmas holiday period and the southern districts thus experienced the unusual phenomenon of a 'white Christmas'. At Manston, Thanet, during the period December 17-24, temperature remained continuously below freezing point for 147 hours, and at Lympne, Kent, similar conditions persisted for 222 hours, apart from a break of a few hours on December 24. At the latter station the maximum temperature on December 20 was no higher than 22° F. Although the period was certainly the most severe since February 1929, the extreme minimum temperatures were not specially remarkable, the lowest so far reported being 7° F. at Dalwhinnie on December 19.

Obituary Notices

Prof. George Barger, F.R.S.

THE sudden death on January 6 of Prof. George Barger, at the early age of sixty years, has come as a shock to all those, in many countries, who were his friends. Barger was born in Manchester in 1878, his father being Dutch, his mother English; and his childhood in a bilingual home, followed by schooling in Holland, laid the basis of that easy fluency in many languages which so distinguished him in later life. He returned to his native England for his university courses, entering King's College, Cambridge, with a scholarship in natural science, after a year at University College, London. In 1904 he was elected a fellow of King's College.

The fact that Barger was placed in the first class in both botany and chemistry in Part II of the Natural Sciences Tripos seemed to leave the direction of his life's work in doubt; but, though his first appointment was as demonstrator in botany in Brussels, under the late Prof. Errera, the researches which he there began were essentially chemical, and included an ingenious and useful method of determining molecular weights on very small samples, by the comparative measurement of the vapour pressures of solutions. His next appointment was as chemist to the Wellcome Physiological Research Laboratories,

where he had already begun some chemical fractionations of the constituents of ergot, when I became associated with him, in 1904, in a collaboration extending over five active and happy years.

The first stage culminated in 1906 with the isolation by Barger, with F. H. Carr, of the alkaloid ergotoxine, which cleared the subject of a confusing competition of impure 'principles', and opened the way to the discovery by others of a series of related alkaloids, extending over the intervening years to the present day. Then came the recognition in ergot extracts of a series of simple, active amines derived from amino acids; tyramine first, and Barger's synthesis of a series of 'sympathomimetic' amines leading from tyramine to adrenaline; and later histamine, which Barger also first isolated from an animal (intestinal) extract, thus opening the way to important chapters in physiology and pathology. Another simple base which has recently figured prominently in physiological conceptions, acetylcholine, was found a few years later in an ergot extract by Barger's former pupil and co-worker, A. J. Ewins, after Barger himself had gone to an academic appointment in chemistry at the Goldsmiths' College, Lewisham, from which, after some years, he passed to the chair of chemistry at the Royal Holloway College, London.

Barger and I became intimate colleagues for a second period, starting in July, 1914, when we joined the staff of the National Institute for Medical Research, then newly projected by the Medical Research Committee. The outbreak of war a month later deferred all normal plans, sent us into temporary quarters, and absorbed our activities in various urgent and largely separate problems. On some of these Barger did work of the highest national importance, which he would have wished to remain unrecognized. Our direct collaboration came to an end with Barger's appointment in 1919 to the chair of chemistry in relation to medicine, then founded in Edinburgh. Circumstances prevented the full realization of the scheme, which was to have put Barger in charge of the chemical aspects of teaching and research in all the medical sciences; but he retained the chair for eighteen years, and made his department an important centre of research in chemistry, often with a medical or biological outlook, to which workers came from most parts of the world.

Of achievements by those who had been Barger's pupils and collaborators in this period, mention may be made of Harington's work on the structure and synthesis of thyroxine, of which the concluding stage was published jointly with Barger; of Stedman's work on the structure of physostigmine, on artificial analogues of that alkaloid, and on the enzyme, cholinesterase, by depressing the function of which physostigmine and its allies produce their physiological effects; and of the work of Todd and his collaborators, on the structure and the synthesis of the vitamin B₁ (aneurine).

Barger, by himself, and with various collaborators from a number of countries, carried on, in the same period, a series of fundamental researches on the structure of certain alkaloids—carpine, galegine, calycanthine and others—and synthesized the amino acid methionine. Though his interests in biology and medicine, and his contacts with workers in those fields, were wide and numerous, he always regarded himself as a chemist, and was especially gratified by recognitions of the importance of his work for chemistry as such, as by the Longstaff Medal of the Chemical Society in 1936, and by the Davy Medal of the Royal Society, awarded less than two months before his death. His position among leading British chemists had been fitly recognized by his appointment, in 1937, to the Regius professorship of chemistry in the University of Glasgow; but he has not lived to show what he would have made of this wider opportunity.

Apart from the numerous scientific papers published in his own name, and by pupils whom he guided and inspired, Barger published two important monographs, both dealing with interests which he acquired during our early association, and later extended. The smaller of these dealt with "The Simpler Natural Bases"; the larger and later one, based on the Dohme Lectures which he gave in Baltimore in 1928, and dealing with "Ergot and Ergotism", is a masterly piece of work, embodying much patient and scholarly historical research, and

showing an unrivalled scientific grasp of the problems presented by a many-sided and fascinating subject.

Barger received many degrees from foreign universities, and was member of a number of foreign academies; but these honours do not in any way indicate the degree to which he became a truly international figure in science. His acquisition of several languages in boyhood made it easy for him to learn others, and he continued throughout life to perfect his command of those he had, at every opportunity of practice, and to seize every excuse, whether of holiday or congress, to add another to his equipment. He had a mind avid for new information and experience, and travelled often and widely, making friends in all countries. He was eager to become familiar not only with the languages, but also with the historical backgrounds and habits of thought of other peoples, and was constantly active to promote international understanding and good will. He gave and received staunch friendship, but, widely beyond the circle of those who enjoyed his intimate confidence, his loss will be mourned in many countries as that of a great figure in science, and of a generous and understanding colleague. There will be widespread sympathy with his widow, his two sons and his daughter, in their tragically sudden bereavement.

H. H. DALE.

Prof. Ferdinand Hueppe

We regret to announce the death in Dresden at the age of eighty-six years of Geheimrat Ferdinand Hueppe, honorary senator of the Technical School of Dresden, who was not only one of the founders of modern bacteriology but also an eminent authority on public health, biology and the medical aspects of athletics.

Hueppe was born on August 24, 1852, at Heddendorf near Neuwied on the Rhine. He qualified in Berlin in 1876 with a thesis on ovarian and abdominal pregnancy, and for the next nine years served as a medical officer in the army, during which period he paid special attention to systematic physical exercise. In 1885 he left the army and founded a Department of Hygiene and Bacteriology in the Chemical Institute of Fresenius at Wiesbaden. In 1889, he was made professor of hygiene in the German University at Prague and held this appointment until 1912, when he settled in Dresden. In 1903 he delivered the three Harben lectures in London before the Royal Institute of Public Health on the etiology of infectious diseases, hygiene and serum, and tuberculosis respectively.

Hueppe was a prolific writer. In addition to a work on the methods of bacteriological research, and another on the forms of bacteria, he wrote on milk, water, typhoid fever, cholera, alcoholism, vegetarianism, and social and racial hygiene. J. D. R.

We regret to announce the following deaths:

Dr. F. P. Burt, M.B.E., reader in stoichiometry in the University of Manchester.

Prof. A. W. Porter, F.R.S., emeritus professor of physics in the University of London, on January 11, aged seventy-five years.

News and Views

Sir Ambrose Fleming, F.R.S.

At the meeting of the Physical Society held at the Imperial College on January 13, Sir Ambrose Fleming delivered an address on "Physics and Physicists of the Eighteen-Seventies", the substance of which appears elsewhere in this issue (p. 99). At the time of the jubilee of the Society in 1924, five of the ninety-nine original fellows were living; now, in his ninetieth year, and enjoying remarkably good health, Sir Ambrose is the sole survivor. Mr. O. J. (now Sir Oliver) Lodge became a fellow in 1875, the year after the foundation of the Society, and was its president from 1889 until 1901. At the inaugural meeting of the Society, the first paper "On the New Contact Theory of the Galvanic Cell" was read by Mr. J. A. Fleming at the invitation of the founder, Prof. Frederick Guthrie. That paper will be reprinted in the Society's *Proceedings*, together with the address he has now delivered after an interval of nearly sixty-five years. This is an event that must surely be unique in the history of learned societies. In addition to his many other honours, Sir Ambrose received the Duddell Medal of the Physical Society in 1930.

M. Bernard Lyot

THE Gold Medal of the Royal Astronomical Society has been awarded to M. Bernard Lyot, of the Meudon Observatory, France, for his observations and photography of the solar corona in the absence of a total eclipse. In 1868, Lockyer and Janssen showed that prominences could be observed when the sun was not eclipsed. In 1882, Huggins attempted the more difficult problem of observing the corona without an eclipse, and both Hale and DeLandres in 1893 designed apparatus for the chromatic isolation of the green line. These efforts were entirely unsuccessful. M. Lyot went much more thoroughly into the optical conditions necessary to eliminate the diffused sunlight. The light of the sun is a million times that of the corona, and at Meudon the scattered sunlight at 1' from the sun's limb cannot be reduced to less than twenty or thirty times that of the corona, but on the Pic du Midi, after a fall of snow, the stray light on occasions is not of greater intensity than the light of the corona at 1' from the limb. But a very large amount of stray light is incidental in the optical systems usually employed, which M. Lyot has analysed into diffraction round the edge of the objective lens, scratches and bubbles on the lens, and reflected light from the back of the lens. By arranging screens to cut off the light from these several sources, he has succeeded in photographing the inner corona, obtaining a spectroheliogram in light 5303 Å., and measuring the polarization all around the limb; in addition, he has obtained accurate wave-lengths of a number of the emission lines of the corona, as well as the width of the lines.

Prof. H. H. Read

PROF. H. H. READ, who has just succeeded Prof. P. G. H. Boswell in the chair of geology at the Imperial College of Science and Technology, London, received his early training in the Royal College of Science under Prof. W. W. Watts. He was appointed to the Scottish branch of H.M. Geological Survey in 1914, but his career was almost immediately interrupted by the outbreak of the Great War. During 1914-17, he was absent on military service in Egypt, Gallipoli and France. In 1917 he was invalided out of the army and resumed work in Scotland, where he remained until 1931. During this period, Dr. Read spent much time in surveying in the central and northern Highlands, and in Shetland, and as a result developed a special interest in igneous and metamorphic geology. In 1929-30, he served as president of the Edinburgh Geological Society. In 1931, he resigned from the Geological Survey on appointment as George Hardman professor of geology in the University of Liverpool. During the last twenty years, Prof. Read has published a number of important papers, mainly on problems connected with the igneous and metamorphic geology of the north of Scotland and Shetland; and in 1935 he was awarded the Bigsby Medal of the Geological Society of London for these researches. He has been chosen as president of Section C (Geology) for the meeting of the British Association in Dundee this year, an appointment which is peculiarly appropriate, in view of his interest in Scottish geology.

Dr. R. L. Smith-Rose

THE Radio Department of the National Physical Laboratory is, as were the two organizations by the fusion of which it was formed in 1933, occupied almost wholly on work within the programme of the Radio Research Board, and Dr. R. L. Smith-Rose, whose appointment as superintendent of the Department was announced in these columns last week, has been associated with the work of the Board from its formation. Dr. Smith-Rose, who was born in 1894, studied at the Imperial College of Science and has, alone and in collaboration with departmental colleagues, published an impressive array of important papers, some seventy in number, on radio direction-finding, the propagation and attenuation of radio waves, the properties of ultra-short waves, the screening of radio circuits and the measurement of radio field-intensity. His principal work has been in the laying of the scientific foundations of radio direction-finding, alike as an aid to navigation by sea and air and as an essential element in studying the properties and propagation of radio waves in general. From the first adequate survey of the accuracy of closed-coil direction-finding, when the

instrument was the main contributor to the quite serious inaccuracies found, he and his co-workers have continued over the greater part of twenty years an advance which has brought them now, using "the most perfect direction-finder in the world", to the estimation of the natural (propagational) limits to the accuracy of practical direction-finding. The greatest individual landmark on this road was the re-discovery and extension of the Adcock system for the reduction of errors due to horizontal electric forces in the received wave front. The National Physical Laboratory may justly be proud of the fact that the principle embodied in every good direction-finding installation in the world to-day is due initially to one member of its staff, Adcock, and owes its great development to two others, Smith-Rose and Barfield.

DR. SMITH-ROSE, whose D.Sc. (London) was conferred for a thesis on direction-finding, was awarded a Student's and a Wireless Premium of the Institution of Electrical Engineers for contributions to its Journal. He is a member of the British National Committee for Scientific Radiotelegraphy, to which he was appointed by the council of the Royal Society, and has been a prominent participant in all the General Assemblies of the Union Radio Scientifique Internationale, save the first. He participated with the British delegation in the Bucharest meeting of the International Consultative Committee for Radiotelegraphy, is a member of the Wireless Section committee of the Institution of Electrical Engineers, and has rendered valued services as vice-chairman (chairman of the staff side) of the Departmental Whitley Council of the Department of Scientific and Industrial Research.

Geological Society: Medal and Other Awards

THE following awards of the Geological Society have recently been made: Wollaston Medal to Prof. F. D. Adams, emeritus professor of geology and palaeontology in McGill University, for his researches on the Pre-Cambrian rocks and on the influence of high temperatures and pressures on the properties of rocks at great depths in the earth's crust; Murchison Medal to Dr. H. Jeffreys, in recognition of the value of his researches on the constitution and physics of the earth's interior, and in particular of the deductions he had drawn from the analysis of records of distant earthquakes; Lyell Medal to Prof. W. N. Benson, professor of geology in the University of Otago, in recognition of the wide range and excellence of his geological researches, particularly in New Zealand; Prestwich Medal to S. Hazzledine Warren, in recognition of his researches on the geology and archaeology of East Anglia, particularly of the Lea Valley; Bigsby Medal to Prof. A. E. Trueman, professor of geology in the University of Glasgow, in recognition of his outstanding contributions to the knowledge of palaeontology and stratigraphy, particularly of the Coal Measures and the Lias; Wollaston Donation Fund to I. S. Double, for his work on the petrology of sedimentary rocks, especially the Tertiary rocks of the east of England, the Glacial deposits, the Chalk and the Trias; Murchison Geological Fund to Dr.

A. L. Coulson, in recognition of his geological work in India, especially that concerned with earthquakes and meteorites and the survey of Rajputana; a moiety of the Lyell Geological Fund to Dr. W. Q. Kennedy, for his petrological work, especially in connexion with the Tertiary complexes of the Hebrides and the metamorphic rocks of the Western Highlands; a second moiety of the Lyell Geological Fund to Dr. A. Raistrick, for his researches on the minute structure and constitution of coal, and on the past floras of Britain as revealed by the study of peats.

Sir Isaac Newton's Prisms

IT is reported from Italy that three optical prisms formerly belonging to Sir Isaac Newton have now found a permanent resting place in the Museum of Treviso. The prisms in question were originally in the possession of Newton's step-niece, Mrs. Conduitt (1680-1739), who spent some fifteen years looking after Newton's house; until her marriage in 1717, to Mr. Conduitt, Newton's successor at the Mint. They were acquired from Mrs. Conduitt by Count Francesco Algarotti, a Venetian nobleman and a prominent figure in London society during the middle eighteenth century. After many changes of ownership the prisms were deposited some years ago in the Treviso Museum, to which institution they were recently bequeathed by the late Prof. Luigi Bailo. Although there seems little doubt that these prisms were at some time associated with Newton, it is not easy to assess what part they played in the fundamental discoveries and subsequent work of Newton on the dispersion of white light. Signor Algarotti was a great admirer of Newton and was the author of "Sir Isaac Newton's Philosophy explained for the Use of Ladies". In the English translation, published in 1739, we learn (vol. 2, p. 70) that Algarotti had found that the prisms available in Italy were unsuitable for repeating Newton's experiments, but that he had been fortunate enough to receive from England some which proved excellent. Later in the same volume (p. 129) we read "I have myself seen the first telescope [Newton's reflecting telescope] . . . preserved in a city of England . . . with this are treasured up those prisms which the first time differently refracted the rays of light in the hands of our great philosopher. . . ." There is no doubt that from about 1664 onwards Newton used many prisms in his experiments and fortunately one of these, at least, is preserved in Great Britain; it was presented in 1927 to the British Museum by the Rev. H. T. Inman, who in a private publication has very carefully traced its descent from Newton. It is made of flint glass, and confirmatory evidence of its date has been adduced from the nature of the glass.

Science and National Defence

THE Association of Scientific Workers, 28 Hogarth Road, London, S.W.5, has had under consideration the position of science in Great Britain in relation to problems of national defence, and has issued a statement defining its attitude. While the Association regards war as the supreme perversion of science, it

is nevertheless prepared to assist in measures for defence against anti-democratic movements. To this end, it stresses the importance of the immediate formation of an organization to see that the most efficient use is made of scientific knowledge; the following points are put forward for consideration:

"(1) It is in the best interests of the country that scientists should be utilized in scientific work, and that the organization and control of scientific work should be in the hands of scientists.

"(2) The professional organization of scientists should play an important part in drawing up and operating any scheme of organization and also be represented on scientific advisory committees to the defence departments.

"(3) In any scheme of registration, scientists should be grouped on a laboratory basis, no matter whether university, special research or industrial. It is particularly important that scientific workers in industry should be included in any such scheme and not left at the disposal of individual employers. Further, scientists should be consulted now with regard to such organization, firstly on the grounds of efficiency and secondly to secure its democratic working.

"(4) Some machinery should be provided whereby scientists, including those in service departments, may exercise a right of criticism on purely scientific and technical matters.

"(5) It is important that scientific and technical as well as medical education should be maintained in time of war."

New Chancellor at the University of Leeds

On January 17, with appropriate ceremony, the University of Leeds installed the Duke of Devonshire as chancellor in succession to his father, who had occupied that post for nearly thirty years, having succeeded the first chancellor of the University, the Marquess of Ripon, in 1909. The proceedings commenced with a lunch to the honorary graduands and to the representatives of other universities and of local education authorities, given by the Court of the University, in the fine new Civic Hall rendered available through the courtesy of the Lord Mayor of Leeds. The ceremony of installation took place in the Town Hall, in the presence of representatives of all sections of the University, and other universities, of local authorities in Yorkshire, together with other dignitaries. His Grace was received by the vice-chancellor, Mr. B. Mounat Jones, who presented him with the scroll recording his admission to the honorary degree of doctor of laws of the University, and then installed him as chancellor, delivering a brief address of welcome. After the chancellor's response, a number of honorary degrees were conferred. Earl Baldwin of Bewdley and the Right Hon. W. S. Morrison, Minister of Agriculture and Fisheries, were presented for the degree of LL.D. The degree of D.Sc. was conferred upon Sir Arthur Eddington, Plumian professor of astronomy and director of the Observatory, Cambridge, upon Sir John Ledingham, director of the Lister Institute, and upon Dr. J. S. B. Stopford, formerly professor of anatomy and now vice-chancellor of the University of Manchester. In the evening, the Chancellor and the Duchess of Devonshire received the guests at a reception in the University, when

many scientific and technological departments were thrown open, special demonstrations being on view. These exhibits remained open for inspection by the general public throughout the following day.

Botanic Gardens of the World

We have received the second edition of the list of botanic gardens of the world compiled under the direction of Dr. Stuart Gager, director of the Brooklyn Botanic Garden ("Botanic Gardens of the World: Materials for a History". *Brooklyn Bot. Rec.*, 27, No. 3, July 1938. Price 2 dollars 50 cents). Apart from its intrinsic value to botanists, the list will prove helpful to research botanists and teachers of botany who may require information or material from definite localities. In this way, the list forms a sure guide. But there are inconsistencies in the information given concerning each individual garden. This is due to the fact that the compiler has been at great pains to make the information authoritative by obtaining it from the source, namely, the gardens themselves. In this, Dr. Gager experienced certain difficulties, since, though most garden officials supplied all the necessary information, some made no or scant reply to the questionnaires sent. Where the information can be considered complete, it is of great utility. For example, under the Royal Botanic Gardens, Kew, are listed date of establishment, area, list of directors, organization, source of income, library, herbarium, arboretum and fruticetum, plantations, publications, museums, etc. The list is not intended to be simply a guide to existing botanic gardens, but as material for a history of botanic gardens, existing or defunct, and "thus as a contribution to one of the most important phases of the history of the organization and administration of botanical science, from the time of Aristotle to the present". Such a history would receive a warm welcome from all botanists, since we believe no such comprehensive history exists at present. We would suggest one slight improvement in the next edition of this list, which would undoubtedly render reference more easy. The gardens are arranged alphabetically under each country, and the latter in turn are arranged alphabetically. There are, however, no page headings (except page number). It would be a distinct advantage if the name of the country were placed at the top of each page.

Folk-lore and Medicine

At a meeting of the West London Medico-Chirurgical Society on January 13, Dr. J. D. Rolleston read a paper on "Folk-lore and Medicine". He said that since the publication in 1927 of the late Dr. Dan McKenzie's work entitled "The Infancy of Medicine: an Enquiry into the influence of Folk-lore upon the Evolution of Scientific Medicine", the subject of folk-lore in connexion with medicine has attracted little attention in Great Britain, in marked contrast with the enthusiasm which it has provoked on the Continent. The various prophylactic and therapeutic measures in folk-lore medicine, in which the curative methods far outnumber the preventive, can be ranged under one or more of the following headings: (1) trans-

ference of the disease to other persons, animals or inanimate objects; (2) animal, plant or mineral remedies; (3) religious influences, including the invocation of special saints; (4) the healing power attributed to water in the form of wells, springs, fountains and streams; (5) the mystical power of odd numbers; (6) repellent and disgusting remedies, including coprotherapy, for the purpose of drawing out the evil spirit supposed to be the cause of the disease; (7) miscellaneous causes, such as the doctrine of signatures, constriction by rings, charms connected with death or the grave, etc. The diseases and symptoms for which the largest number of folk-lore remedies and preventive methods have been applied are whooping cough, 'ague', including not only malaria, but also as its etymology indicates, any acute fever, epilepsy and convulsions of any kind, rheumatism, consumption, eye diseases, skin diseases, especially warts, cattle diseases, headache, toothache, jaundice, hæmorrhages of any kind, and bites of snakes and scorpions. After giving numerous examples of folk-lore medicine in whooping cough, epilepsy, rheumatism and jaundice, Dr. Rolleston concluded by saying that, though many folk-lore remedies have become obsolete, some are still practised, not only by the inhabitants of remote country districts, but also by educated persons in large cities.

The New Deal in Education in the United States

THE Federal Government of the United States seems likely, in future, to play an increasingly important part in the education services of the States. A summary has recently been published ("The Federal Government and Education". Washington, D.C.: Superintendent of Documents. Price 10 cents) of certain findings and proposals of the President's Advisory Committee on Education relating to present conditions with special emphasis on inequalities of educational opportunity, the national interest in education and proposals for federal grants amounting in 1939-40 to 72 million dollars and increasing gradually to 202 millions in 1944-45. The Committee found that "glaring inequalities characterize educational opportunities throughout the nation" and it is argued that federal aid is the only way of adequately remedying this evil. It is pointed out that while the abilities of the States and local communities to provide education have always been unequal, recent changes in social and economic conditions have magnified this inequality and at the same time education has become increasingly important. Fundamentally the inequality is largely due to drainage of wealth, through migration and modern methods of organization of manufacture, commerce and finance, from all parts of the country into the towns and cities and particularly the great metropolitan areas. Hence such glaring contrasts as that between a farm population in the south-eastern States responsible for $4\frac{1}{2}$ million children, with only 2 per cent of the national income, and a non-farm population in the north-east with $8\frac{1}{2}$ million children, and 42 per cent of the national income—21 times as much income from which to educate only twice as many children.

The Josiah Macy, Jr. Foundation

IN a six-year review of the activities of the Josiah Macy, Jr. Foundation, New York, 1930-1936, Dr. Ludwig Kast, president of the Foundation, reports that up to December 31, 1936, the Foundation made 324 grants, amounting to 806,681 dollars, to thirty-four different universities and twenty-seven other agencies for research in the United States, Belgium, Czechoslovakia, France, Germany, Hungary, Netherlands and the U.S.S.R. Special reference is made in the report to the interest of the Foundation in psychosomatic problems, including a survey of the relation of emotion to disease, to its support of investigations upon growth, development, maturation and ageing, the bearing of which upon the changing age distribution of population in the United States and the problems arising from that trend are stressed, as well as in social research concerning health and sickness and medical education. The Foundation in 1933 published the results of a review of the available data and immediate problems in human arteriosclerosis in a volume entitled "Arteriosclerosis: a Survey of the Problem", and the report emphasizes that, in view of the tendency for the age distribution of population to change towards a predominantly older group with a smaller population less than twenty years of age, the problems associated with the ageing of individual men and women are not merely medical problems but also require study by workers in other branches of science, such as economics and sociology. A chronological list of grants is included in the report.

Steam Boilers for Electric Power Stations

CONSIDERABLE progress has recently been made in developing the type of boiler used in electric power stations. It is now generally recognized that considerable economies can be effected by the use of larger steam-generating units, higher steam pressures and higher temperatures. The average capacity of boilers now being installed in power stations has risen to nearly 200,000 lb. of steam per hour. These work in conjunction with alternating current generators giving 30,000-50,000 kilowatts. In the *Electrical Times* of November 24, a description is given by Mr. V. Walker of a number of the latest types of boilers recently installed. Attention is also directed to the alterations made necessary when pulverized fuel is used. Messrs. Babcock and Wilcox have developed some of their boilers so as to take advantage of the economies inherent in the use of high rates of heat release per square foot of furnace now obtainable. They have designed a boiler for the Brighton Corporation so as to have a normal evaporation of 175,000 lb. per hour at 675 lb. pressure per square inch and 875° F. To overcome the difficulties of natural circulation, forced circulation has been developed. Two other types of boiler, the La Monte and the Loeffler, are also being installed in Great Britain.

Recent Additions to the British Museum (Bloomsbury)

AMONG the additions of archaeological interest reported at the meeting of the trustees of the British Museum (Bloomsbury) on January 14, was a

collection of bronze age pottery from Cyprus, which had been excavated by Mr. J. R. Stewart from two graves at Vounous in that island. The pottery belongs to the periods Early Cypriote Ia and Ib, dating from about 2800-2700 B.C., and Early Cypriote IIa, which is placed at approximately two hundred years later. Lieut.-Colonel H. H. R. Deane has presented a collection of examples of Buddhist art, consisting of twenty pieces, mostly small stone figures, belonging to the Gandhara School, dating from the second to fourth centuries A.D. These were collected in the North-West Frontier Province by the late Lieut.-Colonel H. A. Deane.

Recent Appointments in the Colonial Service

THE following appointments in the Colonial Service have recently been made: *Colonial Forest Service*, W. B. Collins, Gold Coast; D. F. Davidson, Cyprus; M. T. Horwood, Gold Coast; F. C. Hummel, Uganda; T. W. Hussey, Nigeria; D. M. M. Kallas, Gold Coast; D. A. Lane, Gold Coast; H. M. Maughan-Brown, Sierra Leone; W. A. Miller, Gold Coast; J. M. Ramsay, Gold Coast; G. G. K. Setton, Fiji; P. G. Shillitoe, Tanganyika. *Colonial Agricultural Service*, C. Harvey (agricultural officer, Tanganyika Territory), senior agricultural officer, Fiji; F. L. Squibbs (director of agriculture, Seychelles), agricultural officer, Gold Coast. *Colonial Geological Survey Service*, J. B. Alexander (geologist, Nyasaland), geologist, Federated Malay States; H. Service (geologist, Gold Coast), geologist, Federated Malay States. *Colonial Veterinary Service*, W. G. Beaton (senior veterinary officer), deputy director of veterinary services, Nigeria; H. J. Lowe (senior veterinary officer), director of veterinary services, Tanganyika Territory; Captain W. L. S. Mackintosh (veterinary officer), senior veterinary officer, Uganda; R. J. Simmons (senior veterinary officer), director of veterinary services, Uganda. *Other Branches*, W. R. Chanmugam (assistant Government analyst), deputy Government analyst, Ceylon; Miss R. M. Henderson, bacteriologist, Veterinary Department, Kenya; G. P. C. Lewis, inspector of plants and produce, Gold Coast.

Announcements

M. L. CLAYMEX, member of the Paris Academy of Sciences and honorary professor of geology at the Collège de France, has been awarded the Paul Fourmarier Prize and gold medal by the Royal Academy of Belgium.

THE Council of the Institution of Naval Architects has awarded the Gold Medal of the Institution for the year 1938 to A. P. Cole, for his paper "Destroyer Turning Circles"; and the Premium to Dr. F. H. Todd and J. Weedon for their joint paper "Further Resistance and Propeller Experiments with Models of Coasters". The Wakeham Prize for 1938 has been awarded to I. C. Bridge for his paper "Structural Stresses in an Oil Tanker Under Service Conditions". These awards will be presented at the annual general meeting on March 29 at the Royal Society of Arts, John Street, London, W.C.2.

THE Gold Medal of the International Faculty of Sciences, which is awarded annually in recognition of outstanding contributions to scientific progress, has been awarded for 1938 to Mr. J. J. Denton, secretary of the Television Society, and vice-president of the Institution of Electronics. The award is in recognition of nearly fifty years' continuous devotion to scientific and technical education.

THE herbarium and library of the Botanical Museum of the Academy of Sciences of the U.S.S.R. are being transferred from Leningrad to Moscow. It is not expected that the new museum in Moscow will be ready for another five years. The Botanical Gardens in Leningrad will be retained.

WE have received a new schedule of fees for tests on volumetric glassware at the National Physical Laboratory which came into operation on December 1, certain modifications in the method of charging being introduced. The tests available and the methods used are described in a pamphlet entitled "Tests on Volumetric Glassware" which, together with the schedule of fees, may be obtained on application to the Director, National Physical Laboratory, Teddington, Middlesex.

THE Educational Advisory Board of the British Social Hygiene Council is holding a Summer School, dealing with "Biology in Human Life", probably at Cambridge, on July 28-August 4. The School will include courses on social biology, and the place of the teacher with regard to the teaching of sex, and lectures by experts on recent developments in the biological field. The course is intended for all teachers, particularly those in senior and secondary schools, who are interested in biological problems as they affect human life and society. Further particulars can be obtained from the Education Officer, British Social Hygiene Council, Tavistock House South, Tavistock Square, London, W.C.1.

THE fourth biennial Child Guidance Conference will be held at the British Medical Association House, Tavistock Square, W.C.1, on January 27-28, when the subjects for discussion will include: treatment of parents, juvenile delinquency, personality deviations and diagnosis of psychoses, the scope of the educational psychologist working in the schools and substitute homes. A session for administrative regulations will also be devoted to the consideration of the findings of the Feversham report on the voluntary mental health services as they affect the policy and administration of the child guidance movement. Further information can be obtained from the Secretary, Child Guidance Council, Woburn House, Upper Woburn Place, W.C.1.

ERRATUM.—In NATURE of December 3, 1938, p. 997, col. 2, letter by Prof. A. Schönberg, last reaction:

Human Cancer and the Theory of 'Cancer Phage'

To explain the observed fact that, in England and Wales for ages above fifteen years, the decrease in deaths from phthisis has been exactly compensated by the increase in deaths from cancer¹, I have postulated the existence of a *Bacillus tuberculosis* 'phage' which is carcinogenic². The idea has been followed up in more detail, and several additional relations of cancer and tuberculosis, all of which support the phage concept, have been disclosed.

If in any age group x persons die of cancer and y of tuberculosis, then the relative tendency of the hypothetical 'complex' of bacillus and phage to break down in the direction of cancer as opposed to tuberculosis is x/y . This 'virulence ratio', R , is a measure of the balance of the 'complex' and becomes the unit of measurement of the theory.

The values of R increase rapidly with age, and from twenty-five years onwards, to a close approximation $R_t = R_{poe} e^{kt}$, a law in harmony with the idea of the phage multiplying within the bacillus. (Fig. 1.)

Fig. 1.

Fig. 2.

The log R law holds for every county of England and Wales and shows systematic variations for the different social classes and for rural, urban and county borough districts.

Two types of ratio may be used:

Cancer
Tuberculosis (R) and Cancer
Phthisis (R_p).

Similarly, two types of section may be chosen, the census unit and the Registrar-General's. For special reasons, the values of k must be calculated from the R values of a census unit section. From the value of K , thus obtained, the period of division of the phages (λ) twenty-five years to old age may be shown to be once in about every 4.5 years. The rate of division has slowly increased during the past century; this can be interpreted as a slowly increasing virulence of the 'cancer phage'.

A second constant of the curves is the 'equi-virulence group', that is, the age group at which $R = 1$. With advancing decennia, the age group at which R is equal to 1 becomes progressively lower. This is a more pronounced change than the alterations

in $\bar{K}_n$, and is interpreted in the theory as due to increased numbers of phages within the bacillus (see below).

The essence of particulate multiplication in geometrical progression must be a discontinuous increase in R . This shows in the values of R for lower age groups. From 0 to 3 years there is an approximate log R law ($\lambda = 6$ months), but from five to twenty years, where $\bar{R}$ remains fairly constant, the verticals do not move progressively to the right in successive decennia but are bunched together into two 'stationary periods' (1851-61-71- and 1891-1901-11-) which are separated from each other by a distinct interval. This is perhaps the most striking new relation in support of the 'cancer phage' theory. (Fig. 2.)

To account for the geometrical progression, values of R must be a direct function of the number of phages. Actually R_s/R_{min} is the number of phages at R_s , and two independent methods of calculating R_{min} give similar results. Using these, it appears that the number of phages present in the undissociated complexes by old age is tremendous.

If values of R represent certain whole numbers (of phages), then the ratios of small determinate values of R should be ratios of integers. These necessary conditions obtain at the stationary periods, where for males

$$\frac{\bar{R}_s (1891-1901-11-)}{\bar{R}_s (1851-61-71-)} = \frac{7}{2} \text{ (actually } 3.491)$$

and for females

$$\frac{\bar{R}_s (1891-1901-11-)}{\bar{R}_s (1851-61-71-)} = \frac{5}{2} \text{ (actually } 2.506).$$

The various regions of the composite curves are named as follows: 0 to 3 years, period of free division; 5 to 20 years, period of arrested division; 20 to old age, period of symbiosis. There is a close correlation between the life-cycle of the complex and the age distribution of pulmonary and non-pulmonary tuberculosis. It is to be noted, too, that early in life, when $\lambda = 6$ months, sarcoma is the chief type of malignancy, while later in life, when $\lambda = 4.5$ years, cancer largely replaces sarcoma.

It is hoped to publish full details of this work shortly.

Egyptian Astronomy

WHILE we are very well informed about Greek and Babylonian astronomy, almost nothing was known of an Egyptian calculating astronomy until very recently. This situation, however, has been completely altered by the discovery and investigation of a number of Demotic texts. In the beautiful collection of Egyptian papyri belonging to the Carlsberg Foundation in Copenhagen, A. Volten found an astronomical text in the Demotic language which he and I have recently edited¹. We were able to show that the text deals with a simple scheme for calculating the beginnings of the months depending on a period of 25 Egyptian years (one Egyptian year being 365 days, this is almost exactly equal to 309

synodical months²). This text belongs to such a late period as Antoninus Pius (c. A.D. 150), it is true; but there are several good reasons for assuming that the same methods were already in use in the Twelfth Dynasty (c. 1800 B.C.³). Thus we know the method by which the Egyptians predicted the phenomena of the moon.

Since then, further essential progress has been made in the understanding of other parts of Egyptian astronomy. Mr. Volten directed my attention to an almost forgotten paper of H. Brugsch⁴, in which he investigated four wooden tablets acquired in 1853 in Egypt by the Rev. H. Stobart, correctly recognizing that these texts refer to the motion of the five planets. These tablets are now in Liverpool and, by the courtesy of the Director of the Museum there, I got excellent photographs of them, making a new investigation of all these texts possible. In this connexion, I would like to express my deep gratitude to the Museum authorities.

The principle of these planetary tablets is easy to explain by means of the following section⁵ belonging to the movement of Mercury:

year 8	10	11	II
		day 25	αβ
	11	10	δ
	12	9	ηξ
		day 29	δ
year 9	1	day 1	δ
		day 12	ηξ
	2	day 6	αβ

The meaning of these numbers is as follows: The years give the years of the reign of Vespasianus (year 9 is, thus, year A.D. 76), and the two following columns indicate the Egyptian months and days on which Mercury enters the different signs of the Zodiac. The only exception to this rule is the information given in the first line of every year. Here only the sign *inside* which the planet is standing on the new year's day is indicated.

To understand the text it is essential to recognize that the same tabulations contain also the *retrograde* entrances of the planet into a Zodiacal sign, a type of movement which manifests itself in the section above by the order δ ηξ δ ηξ. The investigation of these texts becomes as simple as possible if we use a graphical representation showing the velocity of

the planet. Such a graph, for the case in question, is reproduced herewith. For example, this diagram shows without any calculation that the positions of the planet were only calculated theoretically (at least in part), because the point in the middle of the retrograde motion must coincide almost exactly with the inferior conjunction, and in such a position in front of the sun it is impossible to observe a star.

It is easy to date these texts exactly by means of astronomical calculation; we find that they belong to the interval between Vespasianus 3 (= A.D. 70) and Hadrian 17 (= A.D. 132). In addition to the Stobart tablets there is a Berlin papyrus describing the movement of the planets by the same method for the years 14 to 41 of Augustus¹. I intend to publish elsewhere an extensive treatment of all these texts.

Finally, it may be remarked that Dr. H. O. Lange has deciphered an extremely interesting text, also belonging to the Carlsberg Collection, which treats the phenomena of the fixed stars (heliocentric risings and settings, etc.). Thus in an unexpectedly short time we have got a comparatively thorough knowledge of Egyptian astronomy, so that it is now possible to compare Egyptian, Babylonian and Greek astronomy as, for a somewhat longer time, we have been able to compare these respective mathematical systems.

The Expanding Universe and the Origin of the Great Nebulae

It is widely accepted that the system of great nebulae is at present in a state of uniform expansion, the relative velocity of recession between any two members of the system being proportional to their mutual distance. Thus we can write $v = \alpha r$, where the coefficient α has, according to Hubble¹, the value 3×10^{-17} sec.⁻¹. If we accept also the uniformity of expansion with time, that is, if we suppose that the relative velocity of any two nebulae is constant, we can easily calculate that about 10^9 years ago all nebulae were side by side, that is, space was uniformly filled up with the stars. This epoch should thus be considered as the epoch of the formation of stellar accumulations known at present as great nebulae.

Let us consider the necessary conditions for the formation of such condensations in an expanding, originally homogeneous, system of particles with the average mass m (atoms or stars) and average 'thermal' velocity v . Condensations of this kind might be originated by the occasional fluctuations of density, supplemented by the mutual gravitational attraction of slightly condensed particles². If R is the radius of the original condensation, the necessary condition for its formation through occasional distribution of

proper velocities of particles is evidently the requirement that the recession velocity on the surface should be smaller than the proper 'thermal' velocity of particles:

$$\alpha R < v, \quad \text{or} \quad R < v/\alpha \quad (1) \quad (1')$$

As soon as such a rudimentary condensation is formed, the condition for its increase and stability will be given by the requirement that the gravitational potential on the surface is larger than the proper kinetic energy of its particles:

$$\frac{GMm}{R} = \frac{4}{3}\pi R^3 Gm > \frac{1}{2}mv^2, \quad (2)$$

or

$$R > v\sqrt{3/8\pi G\rho} \quad (2')$$

Thus the radii of accumulations should be comprised between two limits. In order that the condensations may be possible at all, we evidently require that

$$\frac{1}{\alpha} > \sqrt{\frac{3}{8\pi G\rho}}, \quad \text{or} \quad \rho > \frac{3\alpha^2}{8\pi G} = 1.4 \times 10^{-17} \quad (3) \quad (3')$$

Since the present average density of matter in space is, according to Hubble¹, only of the order 10^{-28} , the condition for clustering is evidently not satisfied at the present time. However, looking into the past, we find it was satisfied once upon a time. In fact, when all distances were f times smaller, the average density was ρ^f and the value of α was f times larger (on our hypothesis of uniform expansion in time). We write thus:

$$f^2\rho = \frac{3\alpha^2 f^2}{8\pi G}, \quad (4)$$

from which $f \approx 1,000$. Since the present average distance between the nebulae is just about 1,000 times larger than their diameters, we conclude that the time of formation of nebulae coincides with the time after which the formation of condensations became impossible. Thus our picture is as follows: At the early condensed state of the universe, the formation of all different sizes of condensation was taking place. With the progressing expansion, the limits of possible radii were more and more narrowed, and at a certain stage (10^9 years ago) the existing condensation of almost the same radius was dragged apart by expansion. From the present size of nebulae (which we assume to be of the same order as their original size) we can now calculate the velocity v of the particles, and it comes out of the order of magnitude 100 km./sec., that is, of the general order of stellar velocities. Thus it is natural to suppose that the particles we have been considering above were the stars or, in other words, the formation of stars took place before the formation of the great nebulae. If, however, we suppose that the nebulae were originally formed from the gas, 100 km./sec. should be the velocity of gas molecules corresponding to temperatures of several million degrees, which seems to be very unlikely.

We must point out here that our assumption of uniformity of expansion in time can be correct only for the open cosmological models with negative curvature³. The investigations of Hubble¹ seem to indicate, however, that the observed density-distribution of nebulae in space shows thinning out at great distances, thus leading to positive curvature and a closed cosmological model. It should be mentioned, however, that the estimate of distances was made by Hubble on the hypothesis that the absolute luminosities of nebulae remain constant. So far as we

can see very distant nebulae in the earlier stages of their evolution, a slight decrease of total luminosity of a nebula with age will completely change the situation.

A more detailed account of this work will be given elsewhere.

Red Auroral Lines on September 14-16

In a letter entitled "Very Small Intensity of the Red Or Triplet during the Auroral Displays of September 14-16", Vegard¹ has from his observations concluded that the intensities of the red auroral line 6300 Å. and of the red positive group of nitrogen were very weak at that occasion.

Our photographs on Agfa Isopan ISS plates of the auroral spectra on those nights give a quite different result.²

On September 14-15, spectrograms were taken in continuous succession with three different spectrographs from 20^h 45^m M.E.T. until 3^h 55^m simultaneously with photographic height measurements, from a series of stations. On each of the 17 spectra taken, the red auroral lines and bands are fairly strong, and on some of them, the line 6300 Å. is several times stronger than the green auroral line 5577 Å.

In the accompanying reproduction, *a* and *b* show the green and red parts of spectra taken simultaneously with the spectrum the photometer curves of which are given in Vegard's letter; *a* was exposed from 23^h 18^m until 23^h 35^m towards pulsating bands near Vega, *b* from 23^h 43^m until 24^h 00^m towards a red-green band in the north.

On September 15-16, nine spectra were taken, also simultaneously with height determinations. On each of them the red parts are very pronounced; *c* shows the red and green parts of a spectrum taken simultaneously with that taken by Vegard (see spectrum *b* in his letter) from 20^h 47^m until 21^h 52^m towards the summits of sunlit rays near the pole star.

Further Remains of a Sterkfontein Ape

THE discovery at Sterkfontein by Dr. Robert Broom of new fossil anthropoid apes has created such widespread interest that it is desirable to report immediately on all new evidence that may come to hand.

MESIAL AND OCCLUSAL VIEWS OF THE NEW TOOTH
DISCOVERED AT STERKFONTHEIN.

Since March 1934 I have been working in the Sterkfontein district and have been fortunate enough to secure a number of new species of fossil mammals. Early in the present month (December) I discovered on the farm of Mr. Cooper, near the Sterkfontein Caves and about a quarter of a mile away from where Broom's first skull was discovered, a beautifully preserved tooth which differs in many respects from, but yet has certain characters of the same order as, those revealed by some of the upper molars of *Plesianthropus transvaalensis* and *Paranthropus robustus*.

The tooth is an upper left third molar. Its crown measures 13 mm. mesio-distally and 15 mm. buccolingually and its occlusal surface shows little indication of the wrinkling which is such a conspicuous feature of the corresponding molar in Broom's skulls. The crown is triangular in form with the base represented by the mesial side and the angles rounded off. This form is due primarily to marked reduction in the size of the metacone. Compared with the size of the crown, the masticating surface is small. Many of the detailed characters of the grooves and ridges bring to mind conditions shown in the upper molars of *Sinanthropus*. As yet the roots are not completely cleared from their matrix, but sufficient has been done to permit measurement of the height of the tooth from the summit of the paracone to the end of the mesio-buccal root. This measurement equals 21 mm.

It would be unwarranted at this stage to conclude that the tooth represents a different species from either *Plesianthropus transvaalensis* or *Paranthropus robustus*. If, however, it belongs to one of these apes, it is evident that there was very considerable variation in the form of the third molars. I consider the tooth now discovered to be more human-like than the corresponding teeth reported on by Broom, but feel that when assessing the significance of the characters presented both by this tooth and the anthropoid teeth previously discovered at Sterkfontein, it will be necessary to give very close attention to the subject of normal variation of teeth.

Resonance in the External Auditory Meatus

In investigations on the extent to which objective tests can be used to obtain information on the magnitude of the effective amplification hearing aids give to a deaf user, a knowledge of the extent to which resonance occurs in the auditory meatus is of value. In normal human beings such a resonance occurs in the region of 2,000–3,000 cycles per second and to some extent accounts for the shape of the minimum threshold hearing curve as the frequency is varied. It is possible to calculate the magnitude of the resonance from results of mechanical impedance measurements at the opening of the meatus and to demonstrate its existence by means of a probing pressure microphone which indicates increase of pressure as the probe approaches the tympanic membrane. The method has limits, however, and in addition to being inconvenient can cause damage if extreme care is not taken.

Recently a method has been used which permits the measurement of the magnitude of resonance without the introduction of a measuring device into the meatus. It consists in replacing the air in the meatus by some other gas in which the velocity of sound V differs from that in air ($V = 332$ metres per second). The method uses a moving coil telephone receiver which has two tubes of narrow bore inserted through the periphery of the earcap. The receiver is held comfortably in position on the ear by means of a springy headband, the cap of the receiver being covered by rubber to reduce leakage to the external air. One of the tubes is connected to a cylinder of hydrogen ($V = 1,261$ metres per second) and the other tube left free to the external atmosphere. When hydrogen is allowed to pass at a slow rate, by means of a reducing valve, the air in the meatus can be displaced by hydrogen in quite a short time (a minute or so). If the receiver is connected to an attenuator operating on the output of an audio-frequency oscillator, hearing measurements can be made either at threshold or by aural balancing, and the effect of interchange of air and hydrogen quickly determined.

It is found that at frequencies below about 2,500 cycles per second the introduction of hydrogen reduces the intensity level of the sound, the reduction reaching a maximum of about 12 decibels at 2,500 cycles per second. As the frequency is raised further it is found the intensity level first increases as the hydrogen enters, reaches a maximum and then diminishes, while at a frequency in the region of 6,000 cycles the final level is equal to that with air in the meatus. At a frequency of about 9,000 cycles per second, the introduction of hydrogen raises the sound-level by about 9 decibels and at higher frequencies the effect diminishes rapidly to that of a reduction again. The resonant frequencies are not quite in the same ratio as that for the two velocities of sound ($3.8/1$) nor is the increase in level at 9,000 so high as the decrease in level at 2,500 cycles per second. This may indicate that the substitution of a lighter gas in the ear disturbs what might be an optimum reduction factor for the ossicular chain between the tympanic membrane and the oval window, so that there is an overall loss of efficiency due to the change. The initial increase and final decrease in the sound-levels shown in the region from 2,500 to 6,000 cycles indicate that resonance is occurring for air-hydrogen mixtures having values for the velocity of sound intermediate between those for air and hydrogen.

Similar results have been obtained with coal gas ($V = 500$ metres per second), where the two resonant frequencies are closer together, except that the reduction at the air resonant frequency is only about 10 decibels.

The experiments show that there is quite an appreciable pressure magnification (about three times) due to meatus resonance. The flatness of the resonance indicates that energy is absorbed by the material and mechanism of the ear. Undoubtedly some of this energy is consumed in overcoming viscous forces in the middle and inner ear and some of it may be transformed into electrical form in the inner ear.

In addition to the above usage, filling the meatus with hydrogen suggests the possibility of reducing hearing by air conduction near the resonant frequency without corresponding reduction in bone conduction, so far as distant sounds are concerned.

Ultra-violet Absorption of Genuine and Hydrolysed Protein

ACCORDING to the classical theory of protein structure, the carboxyl and amino groups found after hydrolytic splitting of a protein come from $-CO-NH-$ bonds. According to the cyclol hypothesis (Wrinch¹), however, the free carboxyl and amino groups must be formed, during the splitting, from bonds of the

structure $>O(OH)-N<$. The classical theory would predict on hydrolysis no great change in the absorption spectrum below 2400 Å. because the CO groups of the amino acids and of the peptide bonds both are strongly absorbing in this region². On the other hand, the cyclol hypothesis would predict a

greatly increased absorption because of the formation of new CO groups.

We have now compared the absorption spectrum of a genuine serum globulin (ox) with the same protein in the hydrolysed state. 15 c.c. of a salt-free dialysed 4.4 per cent suspension of globulin was dissolved in 180 c.c. $n/12$ $\text{NH}_4\text{OH}-\text{NH}_4\text{Cl}$ (pH 8.9) and sterilized by passing through a Berkefeld filter. To 65 c.c. were then added 45 c.c. of a sterilized 0.17 per cent trypsin solution (Merck) and the mixture (A) was left at 0° C. for 72 hours. Genuine serum-globulin is not digested by trypsin, and therefore another sample (65 c.c.) was denatured in a closed bottle 20 min. in a boiling water-bath. After cooling, pH was the same as before. 45 c.c. of the trypsin solution was added and the mixture (B) left at 39° C. for 72 hours. Sulphosalicylic acid gave then with A a large amount of precipitate, but with B only a faint opalescence. The ultra-violet absorption spectra of solutions A and B are shown in the accompanying figure.

The absorption for genuine (A) and for hydrolysed (B) protein is about equal. This seems to be in greater accordance with the classical theory on the structure of proteins than with the cyclol theory.

Some of the exposures were made at the Hygienic Institute of the University. For this favour we wish to thank Prof. Fridericia and Mr. Behre Jensen.

Mechanism of the Oxidation of Reduced Coenzyme I

The oxidation in animal tissues of metabolites such as lactic, malic and triosephosphoric acids may be resolved into three component reactions:

- (1) Metabolite + coenzyme I $\rightarrow$ oxidized metabolite + reduced coenzyme I.
- (2) Reduced coenzyme I + carrier $\rightarrow$ coenzyme I + reduced carrier.
- (3) Reduced carrier + oxygen $\rightarrow$ carrier.

It was recently discovered^{1,2} that animal tissues contain coenzyme factor (diaphorase), an enzyme which specifically catalyses reaction (2). The chemical nature of the enzyme was not known. The flavo-protein isolated by Straub³ from heart muscle also catalyses reaction (2) and its properties have convinced us of its identity with the coenzyme factor. Under optimal conditions one molecule of flavo-protein catalyses the oxidation of 8,500 molecules of reduced coenzyme I per minute at 38° ($Q_{10} = 180,000$). The catalytic efficiency and the concentration in tissues of this new flavoprotein are sufficiently high to permit the conclusion that it takes a fundamental role in cellular respiration.

Muscle flavoprotein does not undergo a cycle of oxidation and reduction in the course of its catalysis and therefore cannot act as an intermediate between reduced coenzyme and molecular oxygen. There is evidence that under physiological conditions flavo-protein catalyses the reaction between reduced coenzyme and molecular oxygen via the cytochromes.

Coenzyme factor is present in almost every animal tissue and in several micro-organisms⁴. Correspondingly the amount of the flavin-adenine dinucleotide, that is, the prosthetic group of this flavoprotein, is found to be proportional to the amount of coenzyme factor present in the various sources.

A Roman Water Pipe

THE methods used by the Romans in making their lead water-pipes have been described in detail by Lanciani¹ and Gowland². Briefly, a cast sheet of suitable width is bent around a former, so that the edges come together; the inside is then filled with sand, or similar material, a temporary dam is built on either side of the seam and the welding is effected autogenously by means of molten lead or, occasionally, solder. Cross-sections of pipes, when etched in the ordinary way, betray their mode of fabrication, the coarse, crystalline structure of the weld-metal being particularly noteworthy.

ROMAN LEAD WATER PIPE. MICROGRAPH, NATURAL SIZE.

A pipe from the Roman baths at Augst, near Basel, recently examined by me, was exceptional, in that the weld-metal was extremely fine-grained (see accompanying photograph). Its position and the sharpness of the junction with the pipe-metal seemed to preclude the idea that the fineness of grain was due to deformation of the metal, and this was confirmed by the observation that the fine grain persisted after melting and re-casting. On analysis, the weld-metal was found to contain 0.08 per cent of copper (tin absent) and the sheet- or pipe-metal, 0.11 per cent of copper and 0.06 per cent of tin.

The explanation of the structure is now clear in the light of the experimental work, recently published, of Mr. Brinley Jones³, and of some additional information kindly supplied by him. It appears from this that castings of lead containing less than 0.08 per cent of copper (the eutectic proportion) are coarsely crystalline, whereas a higher percentage of copper produces a refined structure, owing presumably to the initial separation of a cloud of minute copper particles, which act as nuclei for the growth of lead crystals. It is essential that cooling should be fairly rapid, so that the copper particles are trapped in the alloy and do not float to the surface, and also that tin should be completely absent. The last condition explains satisfactorily why the pipe metal, though hyper-eutectic in composition, is of unrefined grain.

The useful properties of the metal are dependent, in no small measure, upon the fineness of grain, and I learn from Mr. Brinley Jones that practical use of these lead-copper alloys of fine grain is being made. It will undoubtedly be a source of satisfaction to those who seek application of these alloys to know that they can reckon on the persistence of the fine grain, at atmospheric temperatures, for at least eighteen centuries.

Fig. 3.

CURVED FRACTURE-SURFACE.

With the object of determining the torsional rigidity of plain concrete members, a number of experiments were recently carried out by a research student, Mr. N. Tembe, working with us in the Civil Engineering Laboratories of the City and Guilds College. The majority of the members were 4 ft. in length and 6 in. $\times$ 4 in. in cross-section, except for a distance of 6 in. at the ends, where the section was 6 in. $\times$ 6 in. In addition, some members of circular and of Tee-section were tested.

The concrete was composed of 1 part by weight of cement, 2 parts of fine aggregate (Stone Court sand) and 4 parts of coarse aggregate ($\frac{3}{4}$ in. Thames ballast), the water-cement ratio being 0.55. Two special members were made of mortar consisting of 1 part by weight of cement to 3 parts of Stone Court sand, thus producing a mortar approximating to a natural sandstone or grit in grade composition. Specimens were stored for seven days in moist air before they were tested.

One end of a member was gripped in the fixed 'chuck' of a specially designed testing machine, and the other in the rotating 'chuck' to which the torque was applied. The torque-strain curve for the members was linear, the modulus of rigidity determined from the tests being 2.25×10^6 lb./sq. in. Immediately before failure occurred the twist on a gauge length of 30 in. was approximately $1\frac{1}{2}^\circ$. Failure occurred suddenly by the formation of a tension crack of roughly spiral form, at 45° to the plane of twisting, and immediately after failure there was a relative angular movement of the separated sections of about $2\frac{1}{2}^\circ$ (Fig. 1).

The outstanding features of the failures, namely, the tension crack and the relative angular movement, were observed in every test. The members made of mortar, mentioned above, behaved in a similar manner; members of circular cross-section showed a more perfect spiral fracture. Fig. 2 shows in end view the type of displacement, the side ab being moved to $a'b'$, and Fig. 3 illustrates the curved fracture-surface.

The trace of the fracture-surface on each long face of a test member was inclined at an angle of about 45° to the length of the face. The surface of the fracture was not normal to the face, but had a varying inclination (Fig. 3) and sloped in opposite directions on either side of the centre line of the face. Thus in a broken member, each of the fracture-surfaces, on account of its curvature, consisted of a 'hanging wall' on one side of the axis of torsion, and a 'footwall' on the other side of the axis, to use the terminology applied to faults. When fracture took place, the 'hanging wall' was in each case raised with respect to the 'footwall'.

The concrete broke in tension, but owing to the fact that this was produced by torsional loading, the separation of the two parts involved the motion described above, which would correspond to that of a pivotal reversed fault if it occurred under geological conditions. In text-books of geology, reversed faulting has generally been attributed to compressional forces. A brittle stratum or series of strata in Nature, however, might be subjected to torsional loading, for example, through unequal settlement over an area; the torsional axis in this case would be horizontal (or nearly so). It is suggested that such a loaded stratum would then be likely to break in tension, in a similar way to that seen in the tests described.

Jędrzej Śniadecki (1768-1838) on the Cure of Rickets

It is a view generally accepted that the English physician, Dr. T. A. Palm, first directed the attention of the scientific world to the curative effect of sunlight on rickets. L. J. Harris¹, when dealing with the frequency of the occurrence of rickets in relation to the climate, writes: "The explanation was given by an English medical man, Dr. T. A. Palm, in 1890. He it was who first pointed out that rickets is prevalent wherever there is little sunlight and unknown or comparatively rare wherever sunshine is abundant".

In connexion with the view expressed above, it seems of interest to quote an opinion of Jędrzej Śniadecki about the methods of curing rickets. Jędrzej Śniadecki was a Polish physician and physiologist and professor of chemistry at the University of Wilno. He was the first to introduce into Polish science Lavoisier's then new ideas. The hundredth anniversary of his death was celebrated this year by Polish men of science. In his book "On the Physical Education of Children", written in 1822, Śniadecki says in the chapter on "English Disease": "If the parents' financial status permits, it is best to take the children out into the country and keep them as much as possible in the dry, open and pure air. If not, at least they should be carried about in the open air especially in the sun, the direct action of which on our bodies must be regarded as one of the most efficient methods for the prevention and the cure of this disease. . . . Thus strong and obvious is the influence of the sun on the cure of the English disease, and the frequent occurrence of the disease in densely populated towns, where the streets are

narrow and the dwellings of the working-class people low and very poorly lit."

From the passages quoted above it is quite clear that J. Śniadecki fully realized the significance of the sun both in prevention and cure of rickets.

Marine Turtles as Current Indicators

IN a letter recently published in NATURE¹, my friend Mr. Paul Deraniyagala directed attention to the fact that Kemp's loggerhead turtle, the normal range of which appears to be the Mexican Gulf neighbourhood, occasionally finds its way to the shores of the British Isles; he suggests that: "The possibilities of sea turtles as current indicators would thus appear to be considerable . . ."

A favourable opportunity to test this hypothesis has quickly presented itself, for there has been an unusual number of turtles stranded on the British coasts during the first eighteen days of December. Seven, in all, have been reported. Four of them (two at Bognor, one near Tenby and one on Selsey Bill) were common loggerheads, *Caretta caretta* (Linn.); the others (one at St. Ives, one near Charmouth and one at Bexhill) have not been identified.

Exactly whence they may have come is uncertain, since turtles occur in the tropical and sub-tropical waters on both sides of the Atlantic; but they must have come from that ocean, and it is difficult not to associate their coming with the remarkably warm weather and almost uninterrupted series of south-westerly gales which characterized late November and early December. It seems probable that there has been a strong in-drift of warm surface water into the English Channel from the south-west, but whether there has been that inflow of true Atlantic water which seems so essential for the rehabilitation of the West Country fisheries remains to be seen.

Reproduction of the Dogfish

IN the course of a recent investigation, I have found that:

(1) Migration of ova from the ovary to the coelomic opening of the oviducts in *Scolecophagus ophiocoma* is entirely dependent upon ciliation, as it is in *Amphibia*¹.

The entire peritoneal wall and many abdominal viscera of an adult female are ciliated. The cilia, which are absent in the male and immature female, direct a current of coelomic fluid towards the ostium. An ovum excoiled from the ovary of one adult female and inserted through an abdominal incision into the peritoneal coelom of another will undergo migration towards the ostium. The speed of the migration depends upon the region into which the ovum is introduced. An ovum placed in the bridge joining

the two liver lobes will traverse the hepatic sinus, enter the ostium and descend an oviduct as far as the top of the oviducal gland, in three hours. There are no muscular movements of any of the organs concerned.

(2) In addition to its function of secreting albumen and the egg-case, the oviducal gland of the dogfish is a receptaculum seminis. By triturating a portion of the shell secreting zone of the gland in saline solution, active spermatozoa can be seen at all times of the year. There does not seem to be any sharply defined breeding season, but an increase in breeding activity is noticed in the spring. The oviducal glands of all adult females contain spermatozoa, but the sperm content is very variable. In preparations of resting glands, spermatozoa can be seen in the shell-secreting tubules, whilst in actively secreting glands, a proportion of these spermatozoa are emitted in the shell material. In this way fertilisation of an ovum is practically ensured.

A detailed account of this work will appear later.

Kinetic Regions in Chromosomes

I HAVE previously disavowed any deeply founded conviction concerning the name applied to the kinetic region which, in one form or another, seems to be present in most chromosomes. The first thing needful is agreement on such a name, and then the abandonment of the ten or more other names now in use. I proposed the adoption of the word 'kinetochore', partly because it seems at least as good as any now in use and also because Sharp has employed it in a rather widely used book. But at about that time the term 'centromere' was used by Darlington, and British workers have accepted it quite generally. I should like to point out that not only is thereby added another to the long series of words that already have caused much confusion ('centrosphere', 'centrodesmus', 'centrosome', 'centriole', 'central body', etc.); but that the word 'centromere' was coined by Waldeyer in 1903 to designate the neck region of the spermatozoon. Since it seems certain that many future investigations will concern themselves with the chromosome region in question, I propose that an entirely new name be adopted if the word kinetochore be considered unacceptable.

Points from Foregoing Letters

GRAPHS showing the relation between the incidence of cancer and of tuberculosis in different age groups are submitted by D. Barron Cruickshank. The author connects these with a theory which postulates the existence of a *Bacillus tuberculosis* 'phage' which causes cancer, the relative tendency of the hypothetical 'complex' of bacillus and 'phage' to break down determining how many persons die of cancer and how many of tuberculosis in any age group.

By deciphering an astronomical text in the Demotic language now at the Carlsberg Foundation in Copenhagen, and other texts in the Liverpool Museum, Prof. O. Neugebauer has elucidated some of the methods used by the Egyptians in their astronomical calculations. The texts refer to the dates in which the planet Mercury entered the different signs of the Zodiac and astronomical calculations show that they belong to the period A.D. 70-132; the same methods were probably in use at much earlier periods.

Assuming that the Universe has been uniformly expanding with time, Dr. G. Gamow and Dr. E. Teller calculate that the existing nebulae were dragged apart about one thousand million years ago. Up to that time the nebulae had been together as part of a non-expanded Universe, consisting of particles having a velocity of about 100 km./sec. (of the same order of magnitude as the velocity of the stars, with which the 'particles' may be identical).

Prof. O. Störmer submits photographs of auroral lines taken on September 14-16. Unlike those reported by Prof. Vegard the red auroral lines are

fairly strong and in one instance stronger than the green line.

The discovery of a well-preserved upper left third molar at Sterkfontein, South Africa, more human like than the corresponding teeth described by Broom, is reported by Prof. J. C. Middleton Shaw.

A method of determining the magnitude of the resonance occurring in the external auditory meatus is described by Dr. T. S. Littler. A gas (hydrogen or coal gas) in which the velocity of sound is different from that in the air, is introduced in the meatus, and the change in the intensity level of the sound at different frequencies is observed. An appreciable pressure magnification (about three times) due to meatus resonance was found.

According to F. Haurowitz and T. Astrup, the ultra-violet absorption of genuine and hydrolysed protein seems to be in greater accordance with the classical theory than with the cyclol hypothesis.

Dr. F. B. Straub, H. S. Corran and Dr. D. E. Green have shown the identity of coenzyme factor and the flavoprotein isolated from heart muscle by Straub. This flavoprotein appears to be the normal physiological agent for catalysing the oxidation of reduced coenzyme I.

A photograph of a cross section of a Roman lead water pipe welded by means of lead containing 0.08 per cent copper is submitted by Dr. J. A. Smythe. Owing to the copper percentage being higher than the eutectic proportion, the weld shows a fine grained structure, which has persisted for 18 centuries.

Research Items

East Greenlanders in Olden Times

THE late Knud Rasmussen for many years had contemplated writing an account of the inhabitants of East Greenland before their mode of life had been modified by contacts with civilization, and for this purpose had collected much information, both by personal observation on his expeditions to Greenland, and by conference and correspondence with Christianized Eskimo. His notes and draft for such a work have been edited and published posthumously by H. Ostermann (*Medd. om Grønland*, København, 109, 1; 1938). A topographical record of Eskimo settlements in East Greenland, taking Angmagssalik as its centre, is followed by studies of Eskimo philosophy, religious and magical beliefs, and of East Greenland words, names and expressions. The trading station known as Angmagssalik was called by the Eskimo Tasiussaq, the former name being applied to the whole of the great ford, which extends far into the country, on account of the small fish *angmagssaq*, caught there and there only, to serve as part of the provision for the winter. The inhabitants of this dangerous and inhospitable part of Greenland lived by hunting, the staple of their subsistence being the seal; but they also hunted the bear and, in a lesser degree, other game. If the seal failed them, they ran the risk of starvation; and on occasion so many as fifty per cent of a settlement have perished from this cause, while others have saved themselves by cannibalism, the bodies of those who died being eaten, or, as in certain instances is orally recorded, murder being committed for the sake of the flesh of the victims. While the weather was sufficiently warm to dry the pelts, seals were flensed so as to preserve the skin whole; when dry it was used for the storage of blubber, in which fragments of the meat were preserved—a great dainty. As the weather grew colder, the carcasses were stored whole in the open, the extremities being covered with stones to keep the dogs away. Carcasses preserved in this way might not be eaten for six months, the higher the degree of putridity, the greater the appreciation of those who partook. When the carcass of a seal was brought in to be eaten, all the members of the community shared, the hunter's wife dividing it up, and he and his family usually securing the least share.

Archæology of Eastern Tennessee

IN view of the forthcoming inundation of an area of 56 square miles to the height of the 1,020-foot contour by the building of dams by the Tennessee Valley Authority, it was decided in 1934 to make an archæological survey of the Norris Basin in eastern Tennessee—an area of especial importance for the prehistory of American culture, as the river valley and fertile bottomlands had furnished ideal sites for the rudimentary agriculture of aboriginal man. A report on the results of the survey has been made by Mr. William Webb, who acted as supervising archæologist for the Tennessee Valley Authority (Smithsonian Institution, Washington, *Bull.* 118; 1938). The survey revealed 23 sites showing definite evidence of prehistoric occupation. On these sites there were 20 earth mounds, 9 stone mounds, 4 village sites and

7 caves. Of the 29 mounds, 12 were burial mounds and 17 were associated with prehistoric structures. The sites investigated fall into four or five major divisions, of which the stone mounds had been previously excavated and being largely destroyed, furnished little in the way of archæological data. The cave sites afforded evidence of occupation by a rather primitive people, who buried their dead in or under midden debris on the cave floor. Bodies were usually fully flexed, without artefacts. Bone and shell were used extensively to make simple artefacts. A few burials were after partial cremation elsewhere. These sites seem similar to sites in eastern Kentucky, and with them present similarities to the later components of the Stallings Island complex. The burial mounds in earth have fully flexed skeletons without artefacts. Two are characterized by bundle burial of bones. Of the earth mound and village sites, all with one exception show evidence of rectangular post-mold patterns of dwellings and 'town-houses'. The culture traits here fall definitely into two groups, one showing 'small-log' construction and the other 'large-log' construction. It is suggested, speculatively, that these two cultures are those of people precedent to the Cherokee, by whom elements of the culture were adopted. The early 'large-log' people may be Creeks, while the 'small-log' people were connected with the Creeks by association rather than affinity, and may have been the problematical Yuchi.

Storage of Oranges

PAMPHLET No. 80 of the Australian Council for Scientific and Industrial Research, which has just been issued, contains the results of co-operative work carried out by the Council, the Victorian Department of Agriculture, and the Biochemistry School of the University of Melbourne, and discusses the storage of oranges with special reference to locality, maturity, respiration and chemical composition. High-temperature treatments are not effective in controlling mould development in Washington Navel oranges, but there are indications that such treatments render the fruit less susceptible to mechanical injury and to subsequent low-temperature disorders. Mould development in unjured oranges is a normal disorder of senescence, and any method which aims at its control should be directed towards delaying the senescence of the fruit. Washington Navels picked in early June in the early districts remained palatable for twelve weeks at 40–42° F., and for a further week at atmospheric temperatures. If the fruit was left on the tree longer, the life in cool storage was reduced by an equivalent period. The length of storage life and the rate of progress towards senescence was similar in fruit picked on the same date from both early and late maturing districts, but the oranges took longer to become palatable in the latter case. The development of colour and flavour and loss of acidity were retarded by removal from the tree, whereas progress towards senescence was the same whether the fruit was gathered or not. Palatability was found to depend on the composition of the juice, but respiration and storage life were more closely related to the constituents of the rind. Respiratory activity varied

considerably with the type of orange, that for Washington Navels increasing four times for a rise in temperature of 10°C ., whereas in the case of the Valencia late-orange the increase was only 2.4 times.

Outer Regions of the Earth's Core

In a preliminary attempt to investigate this region of the earth, B. Gutenberg has considered (*Bull. Seis. Soc. Amer.*, 28, No. 3, July 1938, p. 197) the wave *SKS*, also known as *S₀P₀S* or [*S*]. This is a wave which starts at an earthquake epicentre as a transverse pulse, *S*, is transformed as it reaches the earth's core to a longitudinal pulse, *P*, proceeds through the core as a *P* wave, is transformed again at the boundary of the core to an *S* wave and proceeds thus to the station where it is received. The travel time of an *SKS* wave thus depends much on the velocity in the outer part of the core. It is found that the graph obtained by plotting distance, measured in degrees, between the station and the epicentre, against the time of travel of this pulse, begins somewhere between 65° and 90° on the travel time graph of the *S₀P₀S* wave, that is, an *S* wave reflected once at the outer core of the earth, and that the first segment of *SKS* is below *S₀P₀S*. It is thought that *SKS* has a focal point at some distance between 70° and 80° . The extreme values of the velocities of the longitudinal wave in the outer core of the earth appear to be 8.0 and 7.4 km./sec. respectively, though more detailed investigations are proceeding.

Rate of Faulting near an Earthquake Epicentre

An earthquake which has a surface focus might conceivably have a point focus causing subsequent faulting, or might have a line focus, simple or complicated by having the faulting take place synchronously with the initial time of the shock. The former appears, *a priori*, to be the most probable, since the faulting, due to resistance, takes an appreciable time to complete. Taking the former as a hypothesis, Hugo Benioff initiates (*Bull. Seis. Soc. Amer.*, 28, No. 2, April 1938) an instrumental method of determining the rate of faulting and applies it to determine the extent of faulting in the Long Beach earthquake of March 10, 1933, this faulting being invisible at the surface. In a simple vertical fault in which the displacement is perpendicular to the direction of extension, the faulting impulse is considered to be propagated by shear waves. Thus the shear waves from the end-point can never arrive earlier than the wave from the focus. This does not apply where the displacement is parallel to the direction of extension. On these considerations an observed early arrival of *S* indicates that the source is a fault movement in which the displacement is parallel to the direction of extension. This conception can be applied variously, but in the Long Beach earthquake the available evidence indicates that the faulting extended from the focus $\lambda = 117^{\circ} 58' \text{ W.}$, $\phi = 33^{\circ} 36' \text{ N.}$, approximately to Signal Hill, a distance of 27 km. with a faulting speed in the neighbourhood of 4.2 km./sec.

Infra-Red Absorption of Carboxylic Acids in Solution

M. M. Davies and G. B. B. M. Sutherland (*J. Chem. Phys.*, 6, 755; 1938) have investigated at 18° and 75° solutions of acetic, benzoic and trichloroacetic acids in carbon tetrachloride at the three regions of the spectrum where absorption arises from

the O—H, C—O and C=O bonds of the carboxyl group. In each region, double bands appear, one due to the monomeric and the other to the dimeric form of the molecule, and the separation is so small that it suggests that very little change is brought about in the molecule by association. The intensities of the O—H bands of acetic and benzoic acids increase with rise in temperature, indicating a preponderance of monomeric molecules at the higher temperature, thus corresponding with the behaviour of the O—H band of alcohols on rise of temperature. Trichloroacetic acid gives a shift to longer wave-lengths on increasing temperature, suggesting that the O—H bond in this molecule is weaker, in agreement with its behaviour as a stronger acid than acetic. Essentially similar results have been obtained for the other bonds. Different concentrations of acid have been examined, and bond distances for each of the three bonds have been estimated. The same authors (*ibid.*, p. 767) have shown that the integrated intensity of the monomeric O—H and C=O bands give heats of association less than the accepted values, and this is attributed to variation in the absorption coefficient with temperature. In a third paper (*ibid.*, p. 770), Davies has found that α -hydroxyundecanoic acid in carbon tetrachloride at 74° gives two sharp bands at 2.755μ and 2.835μ , corresponding respectively with the alcoholic and carboxylic O—H absorption. From the integrated absorption, estimates of the molar concentration of free O—H groups of each type have been made, and the proportion of free carboxylic O—H is less than that of free alcoholic O—H. The various possible dimeric associations are discussed, and it is shown that, in addition, intramolecular interaction must occur with formation of a cyclic monomer which exists in equilibrium with the open chain monomer.

Nuclear Spin of ^{14}N

ACCORDING to Fermi-Dirac statistics, ^{14}N — ^{14}N should have even-numbered rotational lines strong, whereas in ^{15}N — ^{15}N they should be weak. Two attempts to determine the spin of ^{14}N have just been reported. R. W. Wood and G. H. Dieke (*J. Chem. Phys.*, 6, 908; 1938) found a spin of $\frac{1}{2}$ and that ^{15}N nuclei obey Fermi-Dirac statistics by examining the bands of ^{14}N — ^{14}N produced from ammonia containing approximately 36 per cent ^{15}N . Generally the bands are confused with those of ^{14}N — ^{14}N and ^{14}N — ^{15}N , but the $1 \rightarrow 0$ band of the negative band (N^+) is an exception having its head at 3582.3 A. for ^{14}N — ^{14}N , 3587.4 A. for ^{14}N — ^{15}N , and 3592.5 A. for ^{15}N — ^{15}N . In this last band the *P* branch is free from overlapping by other bands and, on resolution with a 21-foot grating with 30,000 lines per inch and a dispersion of 0.6 A. per mm. , exhibits alternating intensities of successive lines, the odd-numbered lines being strong. C. E. Miller (*ibid.*, 6, 902; 1938) found that it was impossible to obtain a value for the spin of ^{14}N from the rotational Raman spectrum of N_2 , although he obtained good spectrograms from it at four atmospheres with a 20-hour exposure. The difficulty arose from the fact the spectrum contained a very large number of lines due to the three isotopic analogues, ^{14}N — ^{14}N , ^{14}N — ^{15}N , and ^{15}N — ^{15}N . He was, however, able to obtain all the rotational lines from $J = 2$ to 18, and his values are in good agreement with those calculated from theory. The $0 \rightarrow 1$ vibration frequency of nitrogen is 2328.3 cm.^{-1} .

Science Masters' Association

Annual Meeting

THE thirty-ninth annual meeting of the Science Masters' Association was held in Cambridge on January 3-6, under the presidency of Prof. James Gray.

The presidential address—"The Role of Science in Education"—was delivered to about five hundred members. Prof. Gray recalled that at the last meeting Sir Richard Gregory gave a challenge to all those engaged in the teaching of science. In his address Sir Richard said, "Undergraduates are led to believe that their studies in any particular branch of science unfit them for any occupation other than those of teacher, research worker, or technologist in that branch." Prof. Gray maintained this was a challenge which neither the schools nor the universities could ignore. Early in life a boy had to choose the course of his future studies, whether he would follow a literary, a linguistic or a scientific road. Sir Richard Gregory had pointed out that a very small proportion of our administrators are recruited from those travelling along the scientific road because it is alleged that such a path provides an unsatisfactory medium of general education, while administrative ability and an aptitude for science are mutually exclusive. Prof. Gray said that many claims have been made for a scientific education, but they fail to stand up to critical examination. Although the door of the Civil Service is open equally to those trained in any subject, men with a scientific training rarely enter because they are found inadequate as men of the world.

Men of science have long claimed that a scientific education is necessary for life in the modern world, but further investigation has shown that this cold detached attitude is not that required by those having intercourse with the ordinary man. Further, when we claim excellence in observational faculties, investigations suggested that our observation is too limited and specialized, whereas our literary, legal and classical colleagues are better able to detect the solution of human problems: the main difference between the two types of education lies in the attitude towards moral values. The scientist bases his training on a moral code far simpler than that which is deemed adequate for other walks of life. As Sir Richard Gregory said, "Science as such is not concerned with moral values which in the long run determine the policy of the statesman; science is concerned with truth." Men of science may feel glad that this is so, but it may tend to widen rather than bridge the gap between us and our literary friends.

The amazing growth of the Association indicates that, could it but speak with one voice, it could achieve much. If science teachers are to give the best preparation for life to their students, they must give them width of vision and depth of insight, which link together into a natural unity the fields at present separated by unscalable walls. Is it not therefore desirable to bring about a much closer correlation between our scientific training and the matter dealt with on the literary, linguistic and historical sides of school and university? Could not science be less specialized and held together with other studies by

an intellectual cement? One of the greatest barriers to the widened curriculum is the present examination system. But surely, if the Science Masters' Association would state unequivocally what it considers should be the content of examination and other syllabuses faithfully reflecting the teaching which in its opinion is most appropriate, the labour would be well spent.

An interesting lecture, "Terrestrial Magnetism and the Sunspot Cycle" was delivered by Prof. E. V. Appleton. He dealt with the results of observations on the variations of the magnetic elements and their relation to the sunspot cycle. He showed how the explanation of this interrelation, first suggested by Dr. Balfour Stewart, is supported by recent observation.

In a talk on "Arctic and Antarctic Seals and Sealing", Mr. G. O. L. Bertram explained the different species of seals and how the exploitation of two species is scientifically controlled. Other species are virtually extinct due to irrational exploitation and are woeful examples of man's lack of foresight.

Prof. R. G. W. Norrish, lecturing on "Experiments in Photo-Chemistry", delighted a very large audience by the display of a number of spectacular and convincing experiments.

In his lecture, "X-Ray Optics", Prof. W. L. Bragg explained some recent advances in the technique of determining crystal structures. He dealt with the modern method of synthesizing an image, from the experimental measurements of scattering, of the atoms in a crystal, the final pattern having a magnification of 10^5 .

A lecture, "Some Aspects of Geology", by Prof. O. T. Jones aroused interest in a subject which is being more generally recognized to-day in the schools than it has been hitherto. The importance of the subject, particularly on the applied side, was stressed.

Many delightful slides in a lecture of general interest delivered by Dr. H. B. Cott interested a mixed group. This dealt with "Camouflage in Nature and in War". Dr. Cott explained various methods of camouflage adopted by animals for concealment and showed how every scheme of applied camouflage must be based upon the effects employed by animals.

At an open meeting, Mr. N. E. Odell, who has just returned from the 1938 Everest Expedition, gave a graphic description of the events of this last attempt on Everest. He showed how the exceptionally bad weather conditions, in spite of all efforts, prevented the summit being reached.

Mr. H. E. Dance and Mr. J. W. Cottingham opened a film discussion on "Films in the Science Classroom". The opening talks were followed by lively discussion.

The headquarters of the meeting were in the new building of the Department of Zoology. Here were housed exhibitions of books by various publishers and of scientific apparatus by instrument makers. The programme included visits to laboratories and works in the district. Demonstrations were arranged by the science departments of the University.

Lord Horder was elected president for 1939.

Scientific and Industrial Research in New Zealand

THE twelfth annual report of the Department of Scientific and Industrial Research, New Zealand, includes the Minister's statement, together with the Secretary's report, and the reports of the various research committees, institutes or bureaux under the Council. Some account of research work at Canterbury Agricultural College is included, and also of the work of the Geological Survey Branch, the Meteorological Branch, the Dominion Observatory and the Apia and Magnetic Observatories. Referring to the work of the Meteorological Branch, the Minister emphasizes its growing importance as a result of the rapid expansion of commercial aviation within New Zealand and the development of trans-oceanic aircraft. The Geological Survey Branch has gained importance through the Government's proposals in regard to the establishment of an iron and steel industry, and also through the recent activity of oil prospecting, with its emphasis on the importance of accurate data on geological structure and mineral resources of the Dominion. During the year, the Soils Survey Division of the Department has carried out an extensive programme of work in Hawke's Bay, North Auckland, Blenheim, West Coast and Bank's Peninsula, the results of which are being published. The Soils Survey Division has also contributed important data collected in the course of soil surveys which bear on the problem of soil erosion and land deterioration in New Zealand.

These activities fall under the broad section of the activities of the Department which is concerned with provision of essential scientific services to the Government. In this section is also included the work of the Dominion Laboratory, which has recently carried out much work for the Housing Department in connexion with the examination of a wide range of building materials, and has given valuable advice as to the durability and general standard of the materials used. The laboratory is also carrying out important industrial research work, particularly in relation to the phormium, kauri gum and fruit industries, and has almost completed an investigation of the curing of lemons, which has given results of real value to the industry. The work of the Plant Research

Bureau has been further consolidated and is now a major branch of the Department's activity. The Botany Section (now established in Wellington) has been engaged in two major investigations which have a bearing on economic problems—ragwort and South Island tussock grasslands. These studies have revealed the remarkable capacity of the ragwort to regenerate from root fragments, and have indicated that toxic sprays seldom injure the plant to such an extent that regeneration of roots will not occur. The Entomological Division has largely centred on measures designed to control the two principal insect pests of rape and turnip crops and has undertaken a study of insect pests of wheat. Work has also been completed on the effect of Agrosan and Ceresan dusts on the seed of wheat, oats, barley and peas, and has shown that little or no adverse effects can be detected on the treated seeds when stored for periods less than five months, either in subsequent germination or in the control of disease. The Plant Diseases Division has made good progress with spray testing technique, and with the growing of pyrethrum. Attention has also been devoted to problems of industrial mycology.

The Dairy Research Institute has been responsible for important advances in the study of the technique for the maintenance of single strain starters, and in this connexion the experience of the Institute has emphasized the importance of the technical education of managing foremen in industrial efficiency. New research associations have been established to provide a co-ordinated scientific and technical service for the woollen manufacturing, boot and shoe manufacturing and tobacco industries. The newly-formed Social Science Research Bureau has directed its activities to a study of the standard of living of dairy farmers. The study of dietary requirements has been handed over to the Medical Research Council, at a stage where family diets have been formulated giving sufficient energy and protective food values. The report also includes accounts of the work of the Wheat Research Institute, of the Fruit Research and Radio Research, as well as of the work of the Standards Institute.

Protection of the Natives of Dutch New Guinea

MEN of science in Holland have been by no means blind to the havoc which is being caused, especially among fauna and flora, by Western exploitation of natural resources in the remoter parts of the world. They also appreciate to the full the deleterious effects of the impact of Western civilization on primitive peoples. This latter problem is one which has been brought home to them with peculiar force and urgency, not only on behalf of the native populations under Dutch administration in Indonesia, but also owing to the prospective rapid

development of the natural resources of Dutch New Guinea in the near future, where the use of aeroplanes by the great oil interests and also prospecting for minerals are bringing about the speedy opening up of the hitherto inaccessible interior.

On April 28, 1937, the Netherlands Committee for International Nature Protection, an influential body which came into being, as its name implies, for promoting international co-operation in devising measures for preventing or alleviating the grosser and more harmful results in Nature of the spread of civilization

appointed a sub-committee to consider measures for the protection of the natives of Dutch New Guinea. This sub-committee was composed of members eminent in science, or with experience of primitive peoples and of industrial organization in the tropics. Among them were Prof. O. de Vries, of the Government Agricultural Experimental Station at Groningen, Dr. A. J. M. van W. van der Graacht, of the Government Service for the Supervision of Mines, and Dr. H. J. T. Bijlmer, whose expedition to the mountain region of Dutch New Guinea in 1936 effected contacts with native peoples who had never previously seen a white man. The sub-committee has prepared a report, which has been adopted by the main committee and has recently been submitted for consideration to the Governor-General of the Dutch Indies and the Minister for the Colonies*.

The native problem, it is pointed out by the Committee in its report, is twofold. The population of the coastal lands, which on broad lines is already known geographically, consists of tribes of Papuan stock, which already have been in contact with Europeans, official, mission and other, for some decades. These tribes are fierce and warlike, cannibals and head-hunters, among whom murder and manslaughter are rife. Some of them are still uninfluenced by civilization. In the mountain region, until recently almost entirely unexplored, on the other hand, the inhabitants are Papuans of a specialized type, some indeed of so low a stature as almost to warrant the designation of pygmies. Of these a few only had been reached in recent years by scientific expeditions, and that with extreme difficulty, before the aeroplane made the country more readily accessible. The culture of these mountain peoples is of a different order from that of the peoples of the coastal lands. They cultivate gardens and keep pigs, are industrious, and have settled habitations, while their warfare is of a mild type. In disposition they are friendly, and greet European contacts in an amicable spirit.

Two alternative methods of dealing with the native problem presented themselves to the Committee for consideration. Of these the first was the complete segregation of the native population from all contacts with civilization in a native reserve, in which they might be preserved with their culture as museum specimens. The second alternative was the protection of the native population from the effects of a full and sudden impact of white civilization—the abruptness of the impact constituting, it was felt, the essential danger—by a process of gradual preparation and education, in which contact with European influence would be subject to stringent and careful regulation.

The Committee elected in favour of the latter course as the more practical, and at the same time the more fair to the native, as it would leave open to him the possibility of cultural development, from which, it was felt, he should not be debarred, as he would be under the first alternative.

It is, therefore, suggested that provision should be made for three stages of development and contact: (1) a period of gradual reconnoitring and penetration, research and study, with a minimum of native control by Government agencies; (2) a period of gradual building up of a new culture, the introduction of

missions and mission schools, the intensification of Government functions, with a recognition of native authorities, and the extension of communications, and other forms of economic development; and (3) the normal colonial condition of Dutch administration, with co-operation with, and recognition of, local native autonomy.

In order to bring about the smooth development of these three stages of progress, certain regulations are suggested, which include the declaration of population reserves, in which in addition to the existing regulations as to permits for entrance, no Eastern immigrants should be admitted, and no corporate or individual enterprise should be allowed except under special conditions framed to protect the interests of the natives. As a condition of admission to New Guinea, medical examination and precaution against infectious or other diseases should be added to the requirement of a permit; the importation of all alcohol and drugs should be prohibited; and the importation and sale of drapery goods should also be prohibited in order to enforce the wearing of the native type of clothing. Further, the establishment of estates should be subject to regulation, ensuring the preservation of sufficient agricultural land for the needs of the native population, while the importation of labour and recruiting of indigenous labour should be regulated. A large area of the mountain region should be declared a reserve, though not debarred to prospecting, which being for the most part of a transient character should not, under permit, affect the interests of the native population. This large reserve, when known ethnologically, and technically explored, might be broken up into smaller units.

It will be seen that the Committee, in framing its recommendations, has wisely aimed at reconciling the efficient protection of the interests of the indigenous population with the opening up and commercial development of this valuable territory. In framing its policy it has been, as is duly acknowledged, much indebted to the measures taken by the Australian Government for the administration of the Mandated Territory of New Guinea, and above all to the conceptions in native administration of Governor General Sir Hubert Murray.

University Events

BELFAST.—The title of professor emeritus has been conferred on Prof. F. Hummel, who retired recently from the chair of civil engineering.

EDINBURGH.—On January 11, Sir William Bragg formally opened the new common room of the University, situated at King's Buildings, West Mains Road. It is designed to meet the physical and social needs of the students of science, most of whose work is done at King's Buildings. During the ceremony, it was announced that Dr. J. A. Thomson had given £5,000 and promised up to £10,000 towards the maintenance of the building.

Sir William Bragg also took the chair at the inaugural lecture of the newly instituted lectureship of crystallography. The lectureship was founded by a fund left by Lady Dewar, widow of Sir James Dewar, in 1936, and the lecture was delivered by Dr. C. A. Beevers, Dewar research fellow.

Science News a Century Ago

Schools of Engineering, Mining and Surveying

"As very great ignorance seems to exist among the would-be political economists as to the state and progress of the schools for engineering, mining and surveying, we are induced to publish the following remarks:—The Government have the departments at Sandhurst, Woolwich and Chatham; the East India Company have also a college; the Royal Dublin Society have long given regular courses of lectures and instruction, under the superintendence of Mr. Griffiths; and surveying has been so effectively taught at the Agricultural School of Templemoyle, that the Ordnance Survey Department there has received considerable assistance from it. Surveying is one of the regular branches of instruction at Elizabeth College, Guernsey, and we believe also at King William College in the Isle of Man.

"But if any deficiency of these institutions exists it will be fully supplied by the facilities established at Durham and in University and King's College, London. . . ." (*Civil Engineer and Architects' Journal*, Jan. 1839).

Statistics Applied to Medicine

BEFORE the Statistical Society on January 23, 1839, a paper was read by Dr. Guy, professor in forensic medicine, King's College, London, entitled *On the Value of the Numerical Method as applied to Science, but especially to Physiology and Medicine*.

"The success," said the author, "with which calculation has been applied to unorganized matter, and the confidence with which the natural philosopher resorts to it on all occasions, have not failed to exert a powerful influence on those who pursue the study of organized beings, and a growing disposition to apply calculation to the phenomena of life is one of the characteristics of the age in which we live." Having referred to the application of statistics to insurance, crime, bills of mortality, etc., he went on to say that "it often happens that an event is attributed to a cause which varies in intensity under different circumstances or in different localities, and we have no other means of testing the accuracy of our opinion than by comparing the frequency of the event in question, with the varying influence of the assumed cause; and should the same numbers be obtained in every case we are justified in rejecting that cause. If this rule be applied to the received opinions on the subject of phthisis pulmonalis, we should soon see how void they are".

Dr. William Augustus Guy (1810–1885), the author of this paper, edited the *Journal of the Statistical Society* from 1852 until 1856 and served as president of the Society during 1873–75. He was a vice-president of the Royal Society and a founder of the Health of Towns Association.

Geology of Portugal

ON January 23, 1839, Daniel Sharpe (1806–56), a business man who had resided in Portugal, read a paper to the Geological Society "On the Neighbourhood of Lisbon". "In few countries," he said, "can the separation between the tertiary and secondary formations be more strongly marked than in the neighbourhood of Lisbon. The rocks of the latter class were distributed and denuded before the commencement of the tertiary epoch, and a vast mass of

basalt, covering an extensive district to the west and north of Lisbon, is interposed between the youngest of the secondary and the oldest of the tertiary strata". "The 'Hippurite' limestone," he said, "consists in the upper and middle parts of marls and argillaceous limestones, containing layers of flint, and in the lowest of a beautiful hard marble. It occurs only on the Lisbon side of the Tagus." The 'Espichel' limestone is composed of shale and grey limestone. It constitutes the Cape after which it is named."

Sharpe at the time of his death was president of the Geological Society.

Societies and Academies

Edinburgh

Royal Society of Edinburgh, January 9.

F. L. G. RAWLINS: Physical methods in the investigation of paintings (address). A painting, considered scientifically, is an essentially stratified structure, consisting of the support (stone, wood or canvas), the ground (gesso or priming), the paint-film, and the varnish film. These layers may themselves be complex, and they are rarely independent as regards forces of binding, expansion and contraction. Methods of investigation, therefore, have been developed akin to those which have proved valuable in petrology, surface-chemistry and crystal structure. The chief aims of a picture laboratory are (a) the study of condition, (b) study of technique of pure examples of the chief schools. X-rays, ultra-violet and infra-red rays are all of use. Also microscopy, with polarized light, is employed.

K. FUCHS: Invariance of quantized field equations. It is proved that the theory of quantum dynamics as developed by Heisenberg and Pauli is invariant not only against Lorentz transformations but also against all transformations allowed by the general theory of relativity. Although it is impracticable to write the quantized Hamiltonian equations and the quantum conditions in tensor form (the canonically conjugate variables do not form a tensor), it can be shown that the complete system of field equations plus commutation relations does not depend on the co-ordinate system.

Paris

Academy of Sciences (C.R., 207, 1341–1456, Dec. 27, 1938).

H. DESLANDRES: Application to some interesting molecules of the new analysis of molecular spectra.

H. COLIN and M. SIMON: Nitrogen, organates and saccharin richness of the sugar-beet.

F. GRANDJEAN: Neoteny (presence of immature characters in the adult) in the Acarids.

G. GIRAUD: A new extension of the theory of elliptic equations.

J. HAAG: A biharmonic problem.

D. RIABOUCHINSKY: Interpretation of theoretical movements of fluids by 'animated' diagrams.

G. DENIGES: Very sensitive micro-crystalline reactions of bismuth and antimony metalloids.

L. DANIEL: Two new cases of xania in the apple-tree.

H. DAVENPORT: Sums of integral powers.

P. LÉVY: Properties of some indefinitely divisible laws.

P. HEBBONI: Continued two-term matrices and their application to linear integro-differential equations.

J. DELSARTE: Continuous hypercomplex systems and the theory of multi-groups.

L. KANTOROVITCH and A. PINSKER: Partially additive functions in semi-ordered spaces.

L. HIBBERT: The system (R.V.) of integral functions about the essential singular point.

P. DIVE: Barotropic [surfaces of equal pressure and equal density coincident] rotations in the second approximation in a fluid star stratified in ellipsoidal layers.

D. BELORIZKY: Singular points in the limited problem of three bodies.

L. NÉEL: Application to nickel of a new method of measuring the true specific heat.

W. UYTERHOEVEN and C. VERBURG: Temperature of electrons T_e in a positive column discharge with alternating current (50 ~); experimental method.

Mlle. S. VAIL: Silver-platinum comparisons in aqueous solutions of iodides, and electrostatics of the contact Ag-I.

R. FORRER: Decomposition of the elementary moment of ferromagnetics, and the gyromagnetic phenomena.

A. DAUVILLIER: Identification of Hoffmann collisions with electron bundles produced by cosmic rays.

T. KIRI: Remarks on the curves of blackening on [photographic] plates in the region of under-exposure.

G. LILANDAT: Two different examples of the non-additivity of the photo-electric effects of simultaneous luminous fluxes.

C. BENEDICKS: Diagram permitting the graphical representation of the composition of multiple systems, such as those of the light alloys.

A. MAMAN: Contribution to the study of the octanes.

E. LUCATU: Relation between vapour pressure, viscosity and molecular association.

R. VAILLARD: Inflammation of gaseous mixtures by the electric spark: air-diethylether mixtures.

R. LUCAS: Mechanism of fusion.

J. BÉNARD and G. CHAUDRON: Solid solutions of the cubic sesqui-oxide of iron obtained by oxidation of substituted magnetites.

A. PORTEVIN and H. JOLIVET: A mode of decomposition of austenite.

Mlle. D. BIQUARD: Raman spectra of *cis* and *trans* α and β decalones.

Mlle. P. RAMART-LUCAS: Structure of rhodamines from their absorption spectra.

P. CHOVIN: Researches on the Pechmann colouring matters: osimion reactions in the symmetric dinaphthylated series.

R. PAJEAU: Influence of bromides of beryllium, magnesium, zinc and cadmium on the bromination of benzene. They show catalytic activity increasing with atomic weight of the metal, excepting beryllium.

L. DUBREUIL: The Oligocene and the Burdigalian in Syria.

R. FUBON and P. LEMOINE: Presence of the nummulitic at Pondicherry (French India).

L. BÉTRAND: Triassic terrains of the middle part of the Département du Var.

F. BLANCHET: Tectonics of the left bank of the River Durance in the neighbourhood of La-Roche-de-Rame (Hautes-Alpes) and its relations with the Guil nappes.

B. RAJÓSVIÓ: The regime of the sands of the estuary of the Seine.

C. DAUZÈRE: Lightning strokes in the Département de la Haute-Garonne. Frequency of lightning strokes is related to the nature of the soil.

R. GRANDMONTAGNE: Decrease of blue and red light at the end of twilight. Photo-electric measurements show that the red radiation decreases to constant intensity earlier than the blue radiation.

J. MAGROU and J. BOUGET: Presence of mycorrhiza in potatoes reverted to the wild state.

M. BREISTROFFER: An umbellifer hitherto not known in the French flora, *Scandicium stellatum* Thell. of the Baronnies (Hautes-Alpes).

R. FRANQUET: Inulin in grafts of annual sun-flowers and of perennial Composites.

P. CHOUARD and P. VAILLON: Distinct action of photoperiodism on the formation of buds and the development of flowers in the chrysanthemum.

Mlle. S. LALLEMAND: Experimental production, with the aid of colchicine, of strophosomous chicks [with exposed thoracic and abdominal organs, tail applied at the head, etc.].

J. ESCHER-DREHVIKENS, E. LUDMERER and Mlle. M.-L. VERRIER: Researches on the retinal pigments of Cephalopods.

Mlle. V. DANTCHAKOFF: Folliculin in the sexual histogenesis of the embryo of mammals.

J.-H. VIVIEN: Effects of hypophysectomy in a marine teleostean, *Gobius paganelus* L.

Tokyo

Imperial Academy (Proc., 14, No. 8, October 1938).

TSURUBABURO TAKASU: A conformal geometric generalization of geodesic lines.

TATSUO KAWATA: Remarks on the representation of entire functions of exponential type.

TAKESHI IWAGAKI: Remark concerning a problem of M. N. Lusin.

MASAO INOUE: The stability of Dirichlet's problem.

KENJIRO SHODA: (1) Equivalence of representation of finite groups through semi-linear transformations. (2) Invariants of finite groups of half-linear transformations.

KÔSAKU YOSIDA: (1) Abstract integral equations and the homogeneous stochastic process. (2) Mean ergodic theorem in Banach spaces.

SHIZUO KAKUTANI: Iteration of linear operations in complex Banach spaces.

RYOJI SAKATA: Representation of compactness of a sphere.

SABURO NAKANO: Harmonic analysis of nineteen years material of latitude variations observed at some international latitude stations.

KEN SUGAWARA: Dichotomous microstratification of pH. A new type of dichotomous stratification of pH developed in the epilimnion of Takasuka-Numa.

YOSHIKAZU TOYOHARA: Inclination of the strand along a sandy seashore (1).

Forthcoming Events

[Meetings marked with an asterisk are open to the public.]

Monday, January 23

UNIVERSITY OF LONDON, at 5.15.—Prof. R. A. Peters, F.R.S.: "Some Aspects of Vitamin B₁ and Brain Biochemistry".*

UNIVERSITY COLLEGE, LONDON, at 5.30.—Dr. H. S. W. Massey: "The Quantum Theory and Modern Physical Science".*

Wednesday, January 25

COURTAULD INSTITUTE OF ART, at 5.30.—Prof. W. Percival Yette: "Astronomy in Chinese Art".*

Thursday, January 26

ROYAL SOCIETY, at 4.30.—W. J. C. Lawrence, J. R. Price, Sir Robert Robinson, F.R.S. and Lady Robinson: "The Distribution of Anthocyanins in Flowers, Fruits and Leaves".

Friday, January 27

PHYSICAL SOCIETY AND ASTRONOMICAL SOCIETY (Joint Meeting), at 5.15.—Discussion on "The Expanding Universe", to be opened by Prof. G. F. J. Temple and Dr. G. C. McVittie.

ROYAL INSTITUTION, at 9.—Prof. J. D. Bernal, F.R.S.: "Structure of Proteins".

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

LECTURER IN HISTORICAL AND MECHANICAL ENGINEERING in Shrewsbury Technical College—The Clerk to the Committee of Management, County Buildings, Shrewsbury (January 23).

ASSISTANT LECTURER IN BACTERIOLOGY in the West of Scotland Agricultural College, Glasgow—The Secretary (February 1).

TEACHER OF MIXING in Doncaster Technical College—The Secretary, Education Office, Doncaster (February 8).

ASSISTANT LECTURER IN MECHANICAL ENGINEERING in the Manchester Municipal College of Technology—The Principal (February 6).

GUIDE-LECTURER (woman) in Leicester Museum—The Director (February 14).

Finance for Scientific Research

THE publication by the Association of Scientific Workers in the *Scientific Worker* of the final draft of a memorandum on the financing of research, a preliminary draft of which has already been discussed in a leading article in *NATURE* (138, 51; 1938) focuses attention once more upon the provision of finance for, and organization of, research, and the arguments of the memorandum itself and the observations of the Advisory Council upon them deserve close study by scientific workers. A brief survey of the way in which the present position has developed appears elsewhere in this issue (p. 146). The comments of the Advisory Council on the scheme put forward by the Association indicate, indeed, complete agreement with the general thesis that there is need—and urgent need—for much greater application of science by industry. Disagreement with much in the memorandum is based on special knowledge of the difficulties to be overcome, for it is stated that some of the premises upon which the conclusions of the memorandum are based are incomplete and inaccurate.

In the first place, an explanation is given of the way in which Government expenditure on research is limited by the degree to which industry generally is prepared and able to apply scientific method and advance in scientific knowledge. Over a very wide field, though perhaps not necessarily the whole field of science, Government expenditure on scientific research will be largely abortive unless its results are ultimately used in industry, at least in its broadest sense. There are of course branches of research which the State cannot leave to the initiative of industry, such, for example, as work on the preservation and transport of food or the economical use of fuel and the work of the National Physical Laboratory on the application of exact measurement.

It is perhaps pertinent to refer here to one special field which has hitherto largely been left to individual initiative or voluntary support, namely, that of industrial psychology. The success which has already attended the work of the National Institute of Industrial Psychology, demonstrates the valuable service which research in this field can render not simply to industrial efficiency but also to health and safety in industry and in society generally. Work in these latter fields is of course also carried out by the Medical Research Council through the Industrial Health Research Board, with which the Institute has sometimes been associated. In spite of this, the position of the Institute is far from satisfactory. Lack of resources prevents it from pursuing promising lines of work, and the response to its recent appeal has been quite inadequate. Under such conditions the national importance of its work may fairly raise the question of State assistance or development on a much larger scale.

Allowing, however, for such exceptions, though even here the co-operation of industry is often invited and forthcoming, the Advisory Council holds that the worst way of attempting to secure increased expenditure by industry is to spend large sums of public money for its direct benefit in advance. If the importance of securing contributions from industry itself be conceded, the soundness of this view can scarcely be challenged. Indeed certain sections of industry might be in a healthier position had regard been had to this principle before according them the protection of tariffs.

The Advisory Council then proceeds to refute the assertion that fluctuating finance has been a main difficulty. While the Parliamentary Science Committee has probably overstressed the

importance of fluctuations in income—the real trouble is that the general average level of contributions is much too low—the Advisory Council appears to go too far in the other direction. Figures are quoted to show that the net estimates of the Department of Scientific and Industrial Research as laid before Parliament increased continuously from 1929 to 1937, apart from a slight decrease in 1931. The actual expenditure of the Department as given in its annual reports decreased continuously from £740,520 gross or £555,691 net in 1930–31 to £654,736 gross or £451,987 net in 1932–33, increasing again in 1933–34 to £664,482 gross or £476,877 net and thereafter continuously to its present level. These fluctuations cannot be described as violent, nor can they be dismissed entirely as negligible.

On this point, therefore, the difference in the views of the Advisory Council and of the Parliamentary Science Committee appears to be rather in degree than in kind.

As regards the substitution of a fund for a Parliamentary vote, the Advisory Council directs attention to the fluctuations which occurred before the exhaustion of the Million Pound Fund, and deprecates the validity of this argument for replacing a vote by a fund. There is much better ground, however, for criticizing the proposal that the control of the funds for research to be provided by the Exchequer should no longer rest in the hands of the Lord President as minister responsible to Parliament, but in an autonomous body with the Development Commissioners as its nucleus and containing representatives of the learned societies, the universities, medical and agricultural associations, etc. The main reason for employing a minister responsible to Parliament and advised by Government research councils, the members of which are selected on the basis of knowledge and experience as distinct from interests, is the necessity of obtaining a proper balance of research expenditure as between industrial, agricultural and medical research. It is the minister's responsibility to satisfy himself that such a balance is maintained and to that end to submit proposals to Parliament.

The Committee is undoubtedly right in pointing out that Great Britain has lagged far behind Germany, the United States and the U.S.S.R. in providing institutions of this type. The Committee suggests, in particular, institutions for research in optics, silicates and fibres, while chemical engineering, particularly in problems of materials

and unit operations, is a yet further field where a call is for. Institutions of this type would largely be concerned with the long-range or fundamental type of research, and there is no reason to assert, as the Advisory Council does, that, if a vigorous industrial policy in industry is provided, coupled with steady pressure from the Government, they will yield results greatly in advance of the capacity of industry to utilize them.

The Committee then returns to its former contention regarding the fluctuating income for research. It is of course desirable that research should be free to develop without violent fluctuations, and particularly that it should be pursued vigorously in time of depression, when in the past it has been liable to be curtailed. The point is, however, in our opinion insignificant compared with the raising of research contributions from all sources to a really adequate level. Moreover, one of the most important needs of to-day is the consideration of the utilization of research resources from the widest possible point of view. This will almost certainly involve the re-distribution or re-orientation of research effort.

It appears to us, therefore, that the Committee's strongest comments on the Advisory Council's report are its silence on this question of the need for greater co-ordination and on the extension of scientific research into fields which at present make little or no use of it. It is not really possible to separate the two aspects of the problem—the planning or co-ordination and the financing of research. More adequate provision for the finance of research is not more needed to-day than better provision for a really wide view of the national efforts and resources for research with a view to their better distribution, particularly between the physical and the social sciences.

It is probable indeed that this question will be an early consideration of the new Division of the British Association. What will then remain is the question of the authority which can give effect to any recommendations coming from such an influential and representative source. We find no evidence in the present report that the machinery now in existence is incapable of being developed or modified to meet this need without essentially changing its structure. It will be recalled that Sir Daniel Hall's proposal for a Planning Council, intended to pass a technical opinion on proposals submitted to the Cabinet or to Parliament, comparable with the Treasury review which is already provided, contemplates representation in the

Cabinet by the Lord President of the Council, and the ultimate enhancement of his status in the Cabinet.

This appears to us to be far more promising a line of development than that of the autonomous board proposed by the Parliamentary Science Committee. We regard it as essential that any great development on these lines in the expansion of scientific and industrial research should provide, not merely for adequate scrutiny in Parliament, but also for adequate discussion of the financial and technical details in the general sense by technical and professional bodies in general. Despite the excellence of the work of certain public utility corporations such as the British Broadcasting Corporation, the Electricity Commissioners or the Port of London Authority, it cannot be contended that this system provides adequate opportunity for discussion or debate in Parliament, or the information which renders possible informed discussion in the scientific and technical press or elsewhere.

It is no condemnation of the present system that in practice the vote of the Department of Scientific and Industrial Research is normally passed without criticism or debate. That may be merely an indication of the lack of interest which it should be the task of scientific workers to dispel. All the evidence in fact goes to show that the Department is increasingly desirous of co-ordinating its work with that of the Medical Research Council and the Agricultural Research Council, and that the existing machinery should be reasonably adequate if used. Moreover, the Department has already proved its capacity to establish *ad hoc* institutions for special purposes where required as, for example, the Bridge Structures Research Committee, the Steel Structures Research Committee, and the Locomotive Experimental Station Enquiry Committee.

If, therefore, it is conceded that the Parliamentary Science Committee has not made out an entirely convincing case for the establishment of an endowment fund for scientific and industrial research, particularly for the institution of an autonomous authority, neither has the Advisory Council advanced convincing reasons why it should not stimulate research on a somewhat larger scale, and particularly by increased Government grants. It should be remembered that, as the report states, the total expenditure on all kinds of scientific research in Great Britain amounts to only about £4,000,000 a year, or much less than

one tenth per cent of the national income, as compared with one half per cent in the United States and possibly one per cent in Soviet Russia. As has been pointed out from time to time, ultimately Government grants are provided by industry, and if industry is unable or unwilling to provide the required funds directly, increased Government support is merely an indirect means of achieving that end.

It is of course recognized that there are limits to Government effort in this direction, imposed no less by practice than by the educational position of industry as affecting its ability to utilize the results obtained. The field of work of a research association is by no means co-terminous with that of the research department of even the largest industrial firm. In the nature of things its work must be more generalized and less specific than that of an individual research department. On the other hand, a research association is well qualified to undertake the fundamental and long-range investigations which lie outside the scope or resources of even the largest individual research department, and it is precisely in this field that Government help is most desirable.

We do not suggest, of course, that fundamental or long-range research alone should be undertaken by the research associations, or that it is or should be exclusively their task. Much important work of this type is already undertaken by other Government research institutions, such as the National Physical Laboratory, and a strong case could probably be made out for a few more *ad hoc* research institutions. Moreover, such work belongs inherently to the universities also, and in this respect it is highly important that due regard should be had to all existing resources, particularly where, for example, as in chemical engineering, duplication involves the duplication of expensive equipment which may only be imperfectly utilized in any one centre.

Here is a particular case where co-ordination and planning appear to be called for and where some central authority might well on review find the increase in specific grants a sound policy. Never was it more essential to guard against sectionalism and to secure full flexibility if re-orientation and re-distribution are to be possible where required. It may well be hoped that the discussion of the report by influential associations as well as by individual scientific workers, may stimulate further attention to the national financing of research.

Science and its Applications in the Eighteenth Century

A History of Science, Technology and Philosophy in the Eighteenth Century

By Prof. A. Wolf. (History of Science Library.) Pp. 814 + 128 plates. (London: George Allen and Unwin, Ltd., 1938.) 25s. net.

THIS book is the successor of Prof. Wolf's history of science, technology and philosophy in the sixteenth and seventeenth centuries published in 1935, and is planned to form part of a complete history, to be extended in the future both backwards and forwards. The present instalment well bears out the favourable impression created by the earlier volume.

The arrangement of the work may be judged by a list of subjects with the number of pages given to each. Mathematics and physics occupy 297 pages; chemistry, geology and geography, 84; botany, zoology and medicine, 72; technology, 170; psychology, social sciences with economics, 78; and philosophy, 53. Thus it will be seen that most attention is given to the physical sciences and technology. This apportionment is perhaps justified by the relative advances made in the different subjects, and by the author's deliberate restriction of his account of philosophy to the supply of a philosophic background for eighteenth century science.

The book begins with an account of what the eighteenth century inherited from the sixteenth and seventeenth, and then gives a preliminary summary of what was accomplished in the eighteenth. "Enlightenment", born in England in the seventeenth century, spread to France and then to other countries. It involved the new idea of tolerance—freedom for every man to think what he wished and say it. It was believed that Voltaire and the Encyclopædists had established tolerance once for all in the world, to be developed more fully in the nineteenth century. If it were not true, it would be incredible that in the twentieth century half Europe has turned its back on tolerance and freedom, or allowed them to be suppressed by dictators.

The chief work of the eighteenth century in pure science was the acceptance and development of Newton's discoveries. They were spread in France at first largely by Voltaire; they underlay the most important articles in the French encyclopædia, and were carried many stages further towards the end of the century by Lagrange and Laplace. Mechanics and astronomy more and more confirmed Newtonian principles.

After a description of this work, Prof. Wolf

passes to an account of observational astronomy, beginning with Bradley's unsuccessful search for annual parallax in the stars, which led as a by-product to the detection of aberration, and an estimate of the velocity of light. He then deals with other observations, the most important perhaps being the determination of the density of the earth by Maskelyne and Cavendish, and the very prolonged and extensive studies of stars, double-stars and nebulae by William Herschel. From astronomical observation, it is natural to proceed to astronomical instruments, and here Prof. Wolf opens a subject often ignored in histories of science. Scientific instruments not only need great skill in their planning and manufacture, but also enable men to make discoveries and measurements which without them would be impossible. It needs but one example—the determination of longitude at sea by the invention of an accurate marine chronometer by John Harrison.

Next come chapters on the development of light, sound, heat and electricity and magnetism, in which perhaps the most interesting sections deal with Black's work on latent heat and the foreshadowing of the mechanical theory by the measurement of the heat developed in the boring of cannon by Benjamin Thompson, Count Rumford. In electricity, Coulomb established the law of attraction and, towards the end of the century, Galvani started the study of current electricity by observing the movement of frogs' legs when touched with two metals in contact.

In the early years of the century, chemistry was dominated by the phlogiston theory of combustion, chiefly formulated by Stahl. Here Prof. Wolf might have made the essence of the subject clearer. Phlogiston escapes when bodies burn, and, since there is an increase in weight, phlogiston must have a negative weight, a return to Aristotle's ideas. It was the work of Priestley, Cavendish and finally Lavoisier, that explained combustion in terms of ordinary bodies with positive mass and weight, and thus carried the fundamental principles established by Galileo and Newton in mechanics over into chemistry.

The work of Linnæus on systematic botany was followed by that of Wolff and Stephen Hales in plant and animal physiology, the latter subject being greatly influenced by Haller, whose eight-volumed book marked a new epoch. Medicine was developed by a line of medical men ranging from Boerhaave of Leyden to John Hunter of London.

Turning to technology, Prof. Wolf deals successively with agriculture, textiles, building, transport, power and machinery, the steam engine, mining and metallurgy, industrial chemistry, lenses, mechanical calculators and telegraphy. The list shows how wide is the scope of the book. Doubt-

less the description of these "practical applications" will appeal strongly to some readers.

The volume closes with chapters on psychology, the social sciences and philosophy, bringing an able and interesting work to a successful conclusion.

W. C. D. DAMPIER.

Stellar Dynamics

Stellar Dynamics

By Dr. W. M. Smart. Pp. viii+434. (Cambridge: At the University Press, 1938.) 30s. net.

IN the year 1914, when the study of the movements of the stars was in its infancy, a monograph was published by Prof. (now Sir Arthur) Eddington in which was given an account and a discussion of what was known at that time of stellar movements and the structure of the universe. This survey, with its co-ordination of different lines of investigation, undoubtedly stimulated interest in the subject. In the intervening quarter of a century, investigations dealing with the many important problems connected with the movements and distribution have followed at a rapidly increasing rate. But until the publication of Prof. Smart's book, there has been no book in English to take stock of the position and to summarize what has been done.

The volume under review does not cover the whole field. It is concerned almost entirely with the movements of the stars, as may be inferred from the concise title. The related subject of the distribution of the stars receives scant attention. This is to be regretted, because the movements and distribution of the stars are so closely related.

The treatment in this book of the subject of the movements of the stars is mainly mathematical. The observational bases of many of the assumptions that are necessarily involved in a mathematical formulation are not discussed, and the results that follow from the mathematical analysis are not sufficiently compared with the data provided by observation. The Gaussian form of the general luminosity function, for example, is assumed, though it is well known that the observed luminosities show systematic deviations from the Gaussian law, and that the form of the luminosity function changes with galactic latitude. Again, the density distribution in the galactic system is represented by a formula of an analytical character, in which the density is determined by a single variable—the distance from the sun. Such representations of the density distribution were derived by disregarding or smoothing out real irregularities and are approximately valid only within a

relatively small distance from the sun. It is now recognized that there are considerable fluctuations in the density distribution.

The statistical mathematical discussions are not without value and have played their part in the development of the subject. But their limitations are now clearly recognized. Analytical functions do not possess the degree of flexibility that is needed in dealing with the stellar universe, and consequently the analytical methods of the earlier investigations, elegant though many of them were, have largely been displaced by numerical methods. For these reasons, it seems to the present reviewer that many portions of Prof. Smart's book would have been of greater value if the treatment had been less mathematical and more closely related to observational data. In some respects, the book has appeared too late for the method of treatment that has been followed. Ten years ago, the objections to a purely mathematical treatment would not have been so strong.

After an introductory chapter, mainly concerned with an account of the data of observation, four chapters are devoted to the solar motion and the phenomena of star-streaming, the two alternative points of view—that of Kapteyn, of two intermingling streams of stars, and that of Schwarzschild, of a preferential direction of motion—being fully discussed. These chapters contain a good deal of rather heavy, but straightforward, mathematics, and might with advantage have been considerably compressed. The sixth chapter is devoted to the discussion of methods for deriving statistical parallaxes of the stars from their proper motions. This is an important matter, because the zero point for the period-luminosity relationship for the Cepheid variables must be derived from the application of the statistical method to the nearer Cepheids, and the whole scale of the dimensions of the galactic system and of the distances of the external galaxies depends upon the correct fixing of the zero point. There are many traps for the unwary in these statistical discussions, but Prof. Smart is a safe guide.

The space distribution of the stars is discussed in the next chapter, on the basis of one particular

hypothetical law for the density distribution. The mathematical superstructure is too top-heavy for the slender foundations and the results are not of great practical significance. No reference is made to star counts, which provide important information about the space distribution. It may be said that star counts are no concern of stellar dynamics, but neither, in the narrow sense, is the luminosity function, which is much used in this chapter. Star counts are intimately related both to the density distribution and to the luminosity function. In Chapter viii, general statistical methods of deducing certain frequency functions associated with various characteristics of the stars from other assumed frequency functions is discussed; the treatment in the main follows along the lines of the pioneer investigations of Schwarzschild.

A short chapter on moving and globular clusters is followed by three chapters dealing with the dynamics of stellar systems in general, galactic rotation and the dynamics of the galaxy. These chapters are the most interesting in the book, and contain a good account of the recent work of Oort, Lindblad and Plaskett on the rotation of the galaxy, as well as of the explanation of the preferential motion of the stars and the asymmetrical motions of the stars of high velocity. It may be mentioned that the approximate equipartition of energy among the stars is not referred to under the dynamics of stellar systems, and that there is no discussion of the information as to the time-scale of stellar evolution that can be derived from various dynamical considerations.

H. S. J.

Silva and Sentiment

Trees and Men

By Eleanor Hughes-Gibb. Pp. viii+171+11 plates. (London: Alexander Moring, Ltd., 1938.) 8s. 6d. net.

THE sentimental approach to a technical subject is unusual in modern times though common enough in books intended for the juveniles of Victorian days. In a work intended not for the expert, but rather to awaken the public conscience to the desirability of, and in some cases the necessity for, protection of our trees and forests, both at home and throughout the world, sentiment may play a useful part. In skilled hands it can be an effective instrument in a useful form of propaganda, providing it is supported by incontrovertible facts. Much of the information given in the book under review is taken from reliable sources and is pieced together with some skill, but it is unfortunate that many inaccurate or dubious statements have been allowed to stand. Thus, on p. 94, in reference to the cajuput forests of Cochin China, the following appears: "But more important is their invaluable property of absorbing the harmful germs of swamp fever in the soil in which they grow."

The book is divided into three parts, the first of which includes a justification of sentimentality, and such themes as trees of the Bible, tree worship and the economic value of trees. Economic products become "The Gifts of the Tree to Man" and the uncomfortable conditions of a treeless world are conjured up in a fantastic sketch. The second part deals with the manner in which mankind has used and abused these "gifts". Paper-making is given a chapter, which includes an

account of the manufacture of pulp and paper and emphasizes the wastage that occurs in the non-utilization of damaged trees and the lop and top in the forest. Other products discussed include turpentine, rubber and maple sugar.

Several chapters are given up to afforestation in various parts of the world, emphasis being placed on the importance of forests in the conservation of water supplies and prevention of erosion as well as for the maintenance of timber supplies. Some striking examples are given of the devastation caused by forest fires, many of which could be prevented if the public were fully aware of the dangers. The third part, which is given a separate title, "The Life of the Tree", includes a description of the life processes of a tree that is misleading on account of numerous inaccuracies. For example, on p. 145, we are told that sugars are derived from "the carbon dioxide and the moisture of the atmosphere", and on p. 149 we learn that "The green chloroplasts take in the carbon dioxide through the 'stomata'". If the manuscript had been submitted to a competent botanist, such elementary mistakes could have been avoided and the numerous invalid and mis-spelt botanical names corrected.

The book is illustrated by photographs and by a number of drawings by Archdeacon Lonsdale Ragg, who with characteristic touch has caught the beauty and personality of his subjects. The fine avenue of beeches at Tarrant Gunville Manor, which provides the frontispiece, was drawn specially for the book, while the fine old Cedar of Lebanon at the Rookery, Streatham, will be recognized by many Londoners.

R. M.

Racial Fallacies

Lehrbuch der organischen Geographie:
Vorschule und Einführung in das Studium. Von
Prof. Ewald Banse. Pp. ix + 628 + 5 plates.
(Berlin und Leipzig: Walter de Gruyter und Co.,
1937.) 18 gold marks.

THE author claims that his book marks an epoch in the supersession of mechanical by organic thought about the world. It would almost appear that the discovery that "Landschaft und Volkheit" should be treated together is claimed by him as his contribution to knowledge. Surely, not to go farther back, we all acknowledge our debt to Ferdinand von Richthofen and Paul Vidal de la Blache in this matter, the more so as we do not feel that Banse gets as far in that direction as they and others have done. Banse claims that he does not follow out details in the way that 'liberals' would, but makes the presentation of *Ganzheit* (wholeness) his aim. One could wish that he did this more carefully, but for that purpose some insight is needed that he clearly lacks. Looked at as a product of a mechanistic mind, the book has its value as a work of reference for its immense series of definitions. It is regrettable that the author should find it necessary to overstate his own claims, for example, to be the chief author of a system of major regions (1912), dismissing the Herbertson scheme (1905), as a timid effort.

The book begins with physical geography of the still or non-moving *Landschaft* and its evolution under the influence of endogenous and atmospheric influences, and the chief forms it demonstrates to us. One notes that the author includes in this section a review of the facts concerning rivers, lakes and seas, as well as a study of the earth's vegetation. He then proceeds to the moving *Landschaft* which, for him, includes the atmosphere and animal life. Already, in each of these sections, he includes some paragraphs about the relations of man and the various natural phenomena with which he deals. This element in his work would be more valuable were it not for a continual reiteration of the view that war is, apparently, the chief end of life. But that is in keeping with the fashion that the author seems to be so anxious to follow.

Much of the third chief section of the book is devoted to generalizations concerning *Rasse und Volk* as seen in the totalitarian State. A race is defined as a group within mankind which is distinguished from all others by its inalienable heritage of spiritual and corporeal qualities, and

it is stated that it is to be distinguished from a 'folk', within which one finds examples of several races side by side or mixed. It is well to say that the earth's peoples practically all show diverse biological types living side by side. To assert that a supposed spiritual (or mental) heritage is inalienably attached to each corporeal type is pure speculation. This hypothesis is followed by the claim that the language and the energy of will of the Germans are derived from the Fälsch-Nordisch Oberrasse, which has thus given the spiritual, linguistic, cultural and national heritage to the people, but is unfortunately bound to live side by side with other 'races' in Germany. The author makes a special point of 1933 as the beginning of a great advance in the spiritual influence of this Fälsch-Nordisch Oberrasse. One would regret to ascribe to it the cruelties and oppression which have marked recent developments in Germany. Would it not be better to think of the liberalism and toleration so characteristic of the peoples of Sweden, Norway and Denmark as a Nordic feature?

To a Germanophile, these unfortunate characteristics seem rather an example of the mutability of psychological traits under social and political influences. As to the Fälsch-Nordisch idea, it is probably of little use to reiterate that the immense majority of the German people are broad-headed, and that most of the great figures of German life in the past are far from the Nordic type, even if we twist the facts of observation to suit a prejudiced outlook, and call Nordic anyone whose colouring is light. No mention is made of the services of German Jews to German culture.

In the matter of origins of man we find a restatement of the ideas of Klaatsch, which, it has long been understood, he abandoned before his death. The notions of a separate descent of man from perhaps even Palaeozoic ancestors, of an infinite gulf in descent separating white men from Africans and so on, are all expounded in a not very skilled fashion, and unfounded claims about Fälsch-Nordisch origins of cultural features are implicit as well as explicit in many paragraphs.

The German people have a great tradition; their contributions to civilization have been outstanding in almost every field. It is to be hoped that German thought may yet recover from the petty vanities and prejudice that have affected so much of it in recent years.

H. J. F.

Enzyme Chemistry

Kurzes Lehrbuch der Enzymologie
Von Theodor Bersin. Pp. viii + 170. (Leipzig :
Akademische Verlagsgesellschaft m.b.H., 1938.)
12.80 gold marks.

DR. BERSIN'S interesting book covers a very large field in a very small space and he is to be congratulated on the brevity, clarity and, on the whole, the accuracy of his exposition. The book is highly condensed, probably too much so for those with little acquaintance with the subject, and whilst general analytical or mathematical treatment is restricted to the barest outline, prominence is given to some of the remarkable advances which have been made in the field of enzyme chemistry during the last few years.

The subject-matter is divided into three sections. The first is concerned with the general properties of enzymes, the second (taking up about half the book) is concerned with the properties of individual enzymes, and the third has to do with a much too brief treatment of the parts played by enzymes in respiration, nutrition and metabolism.

Dr. Bersin's conception of an enzyme is a generous one. He includes in his classification such substances as cytochrome and flavoprotein. It is not clear what is his justification for this procedure, especially as he states that the activation of a substrate by an enzyme takes place only at certain suitable areas (*aktive Gruppen*) of the enzyme surface. One would like to know what substrate molecules are specifically activated by cytochrome or flavoprotein; there is no indication of their nature in Dr. Bersin's book. It is characteristic, however, of the state through which a certain section of enzyme chemistry is now progressing that prominence is given to the nature and functions of prosthetic groups (coenzymes) rather than to the specific proteins which are the actual activating agencies of the substrates that undergo change. This is entirely to be expected, for it is only recently that the chemical nature of these prosthetic groups has been elucidated. Yet there seems to be a definite danger that the significance of the special protein to which the substrate molecule is specifically attached is being overlooked; certain it is that the importance of the specific protein is at present overshadowed by that of the 'prosthetic group'.

Dr. Bersin deals shortly in the first section of the book with such topics as the protein nature of enzymes, enzyme reactions in heavy water, enzyme kinetics, optical specificity, temperature effects,

enzyme formation in the cell and with some other topics relevant to a chapter on the general chemistry of enzymes. He has but little to say, however, on the recent work on adaptive enzymes, on the reversible inhibitors of enzymes, on the protective influence of substrates on their enzymes, and it is surprising that, in a text-book of this nature, details concerning enzyme equilibria (for example, with the dehydrogenases, fumarase, aspartase, etc.) are absent.

Dr. Bersin proceeds to deal at greater length with esterases (considered, however, very scantily), carbohydrases, amidases and proteases. Due prominence is given to the recent work on the crystallization of proteolytic enzymes, useful descriptive procedures are noted and care is taken to impress the reader with the importance of the thiol groups in the activity of papain. It should, however, be pointed out that Bergmann and Ross have shown that the activity of papain cannot be interpreted solely on a $-SH$, $-SS-$, basis. The section is terminated by chapters on carbonic anhydrase, carboxylase and the reduction-oxidation catalysts. These are fairly adequately treated considering the space at Dr. Bersin's disposal, but there are many omissions (for example, carrier linked reactions, amino acid oxidases) and there are several points where criticism may be directed.

Dr. Bersin states, for example (p. 124), that disulphide-thiol systems (for example, glutathione, cystine) act as hydrogen acceptors to the succinic acid dehydrogenase system. There is no evidence for the truth of this statement. Moreover, he states that succinic acid enters into an equilibrium with its dehydrogenase giving rise to fumaric acid and a reduced form of the enzyme. The latter is held to be not autoxidizable but to reduce cytochrome. Such a statement is at present without direct experimental support, and the text-book under review seems scarcely the place to make such a statement without some sound evidence to support it. A similar criticism may be directed against the inclusion (p. 119) of glyoxalase as a system consisting of two dehydrogenases, flavoprotein and another, unknown, factor.

Dr. Bersin's book would have been improved, especially for those for whom it claims to be a guide, by the inclusion of more references to original articles. The total number of references cited is just over a hundred, of which one third are references to review articles in the *Ergeb. d. Biochemforschung*. The book is well printed and free from typographical errors. J. H. Q.

Die Binnengewässer

Einzeldarstellungen aus der Limnologie und ihren Nachbargebieten. Herausgegeben von Prof. Dr. August Thienemann. Band 16: Das Phytoplankton des Süßwassers, Systematik und Biologie. Von Dr. G. Huber-Pestalozzi. Teil 1: Allgemeiner Teil, Blaualgen, Bakterien, Pilze. Pp. v+342. (Stuttgart: E. Schweizerbart'sche Verlagsbuchhandlung. (Erwin Nägele, 1938.) 42 gold marks.

BRITAIN took the lead at one time in the making of big books of reference in botany and natural history; this was in the days, for example, of Bentham and of Hooker, of the *Challenger* Reports and of the British Museum Catalogues of Birds and of Fishes. But nowadays the Germans seem to have it all their own way, and here, drawing at last to a close, we have the sixteenth volume, or part of it, of the great work on "Die Binnengewässer", or what we have learned to call limnology, which the late Einar Neumann of Lund and Prof. Thienemann of Kiel began to publish a dozen years or so ago.

This last part, by Dr. G. Huber-Pestalozzi, deals with the phytoplankton, or so much of the fresh-water flora as floats or swims; and as the present volume includes neither the diatoms, nor the desmids, nor the Volvocineae nor many more, there is still a deal to come. In fact we have here only the free-living bacteria and a few fungi and the blue-green algae or Cyanophyceae, with a hundred pages of introductory matter thrown in. The account of the Cyanophyceae covers 150 pages and is very fully illustrated; as a compendium of many important genera, *Nostoc*, *Oscillatoria*, *Anabaena*, *Lyngbya* and the rest, it is all that could be reasonably desired. The introduction deals with many points of general interest. It divides the plankton into plankton proper and the so-called 'neuston'—a term new to us—which means the organisms the peculiar province of which is the surface-film; here various minute plants accumulate, here *Gyrodinium* and *Ranatra* skate on top, and here *Scapholeberis* clings on below. A long chapter deals with *Schwebestheorie*, that is to say the conditions of magnitude, form and density which fit the organism for a floating life, and cause or help it to shift its place and depth according to time and season. Here Dr. W. Ostwald's well-known work, and that of other writers on the physical side, is duly dealt with; but this side of the case is by no means easy, and the author is more at home on the other.

Our Wandering Continents:

an Hypothesis of Continental Drifting. By Dr. Alex. L. du Toit. Pp. xiii+366. (Edinburgh and London: Messrs. Oliver and Boyd, 1937.) 18s. net.

THE author is to be congratulated upon a brave project, the writing of a geological history of the earth in terms of continental drift. He has unrivalled credentials, based upon a special knowledge of South Africa, combined with comparative study of that sub-continent and South America, and with extensive travel in many other lands. His introductory chapters include useful summaries of the writings of Taylor, Baker and Wegener, to

mention but a few. Then follows the Palaeozoic and Mesozoic story of Gondwana and Laurasia, considered separately. The Carboniferous glaciations and *Glossopteris* flora of the former receive due consideration. More novel is a synthesis of the Samfrau geosyncline, named after South America, South Africa and Australia.

The subsequent history of the lands of the world as a whole is grouped geographically about the great double fold-girdle of Tertiary mountains, which in its southern loop embraces the scattered segments of Gondwana, and in its northern loop, those of Laurasia. Later chapters deal with such topics as oceans, the significance of chemical changes leading to condensation in depth, climatic changes, distribution of plants and animals, geodetic evidence, and, of course, possible causes of continental drift.

Readers should be warned in advance that they will find du Toit's book difficult to digest, and that they may feel affronted by uses that have been made of fragmentary evidence. On the other hand, it is to be hoped that they will have sufficient vision to be grateful to a courageous pioneer. E. B. BAILEY.

Botany for Fun

By Gareth H. Browning. Pp. xii+176. (London: Lindsay Drummond, Ltd., 1938.) 5s. net.

THIS delightful book is not intended as a text-book, but is designed to engage the interest of young readers in the study of plant life. With this aim in view, the author has adopted a unique style of writing which forces itself upon the reader so that he almost learns without thinking. Technical terms, though not altogether excluded, are relegated to the background, and though the style of writing is attractively conversational and non-scientific in the technical sense, no one would condemn the author for that. The teaching botanist would agree that such chapter headings as "Magic in the Factory", "Flower-Parents and their Children", "Adventuring into the Outer World" and "Family Gatherings" convey just the right shade of meaning to the child-mind.

It is very difficult to write in this style yet not stray from the path of scientific accuracy; but careful scrutiny shows that the author has succeeded in surmounting this difficulty. We are glad to see, for example, that the author writes of "food materials passing up from the roots to the leaves" and of the "stream of *manufactured* food" travelling from the leaves. He even goes so far as to emphasize the important words by using italics. Many botanical texts are guilty of erroneously referring to mineral salts, carbon dioxide, etc., as plant *foods* so that it is very difficult to teach children the essential similarity between plant and animal foods.

The illustrations are good and the interpolation of interesting historic episodes adds much of value to the whole.

Though the author emphasizes that this is not a text-book, we venture to suggest that it might with distinct advantage be adopted in classes of children of about eleven years of age.

(1) *Unit Processes in Organic Synthesis*
By P. H. Groggins (Editor-in-Chief). (Chemical Engineering Series.) Second edition. Pp. xiii+769. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 36s.

(2) *Industrial Chemistry*
By William Thornton Read. Second Edition. Pp. ix+605. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 25s. net.

THE very rapid development of the chemical industry in the United States, which country probably leads the world to-day in this respect, has brought about a demand for trained chemists both on the research and on the factory side. The magnitude of the profession is witnessed by the fact that the American Chemical Society has a membership of more than 21,000 and has enlisted more than 2,000 new members per annum for the last three years. It is becoming customary for students entering on the factory side to take a course in chemical engineering. It was stated last summer that rather more than half the chemical graduates do this. In consequence there is a demand for chemical engineering literature both of a general and a specific character, and to-day America is well served in this respect. The demand for such books enables them to be kept up to date, an important factor in a rapidly developing science.

Both these books are second editions, that of Groggins after four years. It deals with unit processes in the organic industries, many of the individual chapters being contributed by experts, as is now the custom. The new enlarged edition is likely to enhance the reputation of the work.

Read's book has likewise received expert criticism, the individual chapters having been sent to more than a hundred authorities in the particular fields. The sections relate to individual branches of the industry, a wide range being included. With these two books on his shelves the trained chemist is well equipped to tackle problems in any branch of the chemical industry.

Summable Series and Convergence-Factors

By Prof. Charles N. Moore. (American Mathematical Society, Colloquium Publications, Vol. 22.) Pp. vi+105. (New York City: American Mathematical Society, 1938.) 2 dollars.

THIS work is designed to give a systematic treatment of convergence-factor theorems, where these consist of results concerning the relationship between a definition based on mean-values and a formally distinct definition in terms of convergence-factors. For all the methods of summing divergent series in general use may be classified as either mean-value or convergence-factor methods, and to any method of either type, a formally equivalent method of the other type can be constructed. The range of validity of these methods is approximately the same in most cases; and where there is a difference, it will usually be in favour of the convergence-factor form.

Here, two types of convergence-factors are considered. Those of Type I have, as sole object, the maintenance and production of convergence; while those of Type II may be used to obtain the sum of

a series. In this most instructive work, both types of convergence-factors are examined; and the theory is developed for multiple series of any order, as well as for simply-infinite series. By means of the use of the Norlund, instead of the Cesàro means, the theory developed here is more general than that found in most of the available literature on the subject. Thus, many previous results appear here as special cases of the theorems proved—particularly in the third, fourth and fifth chapters.

A. V. Z.

Rezeptbuch des Alltags

Von Dr. Hermann Rompp. Auflage 3. -Pp. 349. (Stuttgart: Franckh'sche Verlagshandlung, 1937). 8.50 gold marks.

THE word *rezept* is liberally interpreted, and this book includes prescriptions for dealing with all the problems that are likely to arise in an ordinary household. It gives directions for making emetics, hair dyes, shampoos, face creams, eau de Cologne, mouth washes, shaving soap, alcoholic drinks, boot polish and about ten kinds of ink, and for treating colds, warts, nose-bleeding, sea-sickness, heat-spots, sunburn and indigestion. Sections are devoted to the keeping of horses, cows, dogs and cats, and to getting rid of mice, rats, earwigs, ants, snakes and a host of other pests that afflict houses and gardens. There are sections on gardening, photography, food and clothes. The information appears to be accurate and up to date.

A Course of Physics

By Prof. Henry A. Perkins. Pp. ix+820. (London, Glasgow and Bombay: Blackie and Son, Ltd., 1938.) 15s. net.

PROF. PERKINS, of Trinity College, Hartford, has written a text-book of elementary physics covering more ground than is usual. His aim has been to give the student a substantial grasp of physical principles rather than to describe phenomena. Simple algebra and trigonometry have been freely used because most students find a concise symbolic statement easier to grasp than a verbal one. Modern physical ideas have been treated as fully as is feasible in a course of this kind, and nearly eighty pages have been devoted to 'corpuscular physics'. The book should prove suitable for an intermediate science examination in Great Britain.

The Cradle of the North Wind

By A. S. T. Godfrey. Pp. xi+234. (London: Methuen and Co., Ltd., 1938.) 8s. 6d. net.

THIS charmingly naive book gives a glimpse of the fun which, according to the author, may be derived from roughing it in the Arctic and from killing its animals, always with the proviso that there is not too much "scientific nonsense" about. It must, however, be remembered that the penalty for a frivolous attitude of mind towards the polar regions is very likely to be death, and not for one's self alone: the ice is not suitable for a kindergarten. It is a little surprising that such a book should presumably have been sanctioned by the Oxford University Exploring Club.

J. E. HAMILTON.

The Sea-Bird as an Individual: Results of Ringing Experiments*

By R. M. Lockley, Skokholm Bird Observatory

SKOKHOLM ISLAND lies a few miles off the coast of Pembrokeshire. It is about 240 acres in extent, is entirely rock-bound, and has only two houses on it, a lighthouse at the most westerly point, and this is a mile from my own house on the east side of the island. The cliffs are of Old Red Sandstone, and there is a good thick soil on the greater part of the island.

I was attracted to the island in the first place by its great wealth of sea-bird life. Later, as opportunity afforded, I commenced to look into the individual lives of these birds. The first essential in such a study, since individual sea-birds of one species are more exactly alike than peas in a pod, was some method of marking. I adopted Mr. Witherby's scheme for marking birds with numbered leg-rings. This scheme has now been taken over by the British Trust for Ornithology and is housed in the British Museum (Natural History).

There are seven sizes of rings to suit all species of British birds from a wren to an eagle. Each ring has a serial number and the inscription "Inform British Museum (Natural History), London"; so that those who capture alive or find dead a bird with such a ring will know what to do in the interests of scientific bird-study.

I started my study of the individual sea-bird with the Manx shearwater (*Puffinus puffinus* (Brünn.)), the habits of which were at that time very little known. There are probably ten thousand pairs breeding on Skokholm. The shearwater nests in a hole in the ground, sometimes deep in a rabbit-hole, but it will also excavate a hole for itself in soft ground. A small colony nested in shallow burrows within a few yards of my back door. So it was not difficult for me to trace with a stick the winding of the burrow to the nesting recess at the end, and to cut out a turf immediately above the nest, and then to use that turf as a convenient inspection lid.

By degrees my wife and I were able to work out something of the Manx shearwater's life-history. The burrow would be inhabited so early in the year as February, the paired birds meeting each dark night as if they were determined to make sure of their nesting territory for another season, although the egg would not be laid until late April or May. Ringing has since shown us that the old breeders always arrive first.

Sexes are indistinguishable in the field, but in some cases we knew the female by finding her on a new-laid egg. In any event both birds were ringed. Only one egg is laid, and incubation is equally shared. Thus the male, for example, would spend two, three or four days on the egg without quitting the burrow. Then the female would take over. On dark nights, the bird at sea would return and converse with the sitting bird for an hour or two, but would not necessarily relieve it. Nor could we get any evidence that it fed its sitting mate. We came to the conclusion that the sitting bird stuck to the egg as long as hunger permitted, or as long as it could retain possession of the egg against its mate's determination to brood it. This at least appears to be the explanation of the irregular shifts or watches by one or other of the pair on the egg on dark nights.

On moonlit nights, however, this ardour to incubate was cooled by what we presume must be the bird's fear of being seen and killed by the many predatory gulls and hawks which frequent the island. So when a period of moonlit nights intervened, the bird at sea never visited the bird on the nest. Thus for five, six, seven, and more rarely up to ten, and once twelve, nights and days when the moon happened to be near or at the full, and the skies cloudfree, the sitting bird remained brooding but starving at the nest. We even weighed some of these starving birds and proved an average loss of a very small fraction of an ounce every twenty-four hours. Starving is really the wrong word, though at the time it seemed appropriate enough. Now we have found that a sea bird can easily endure long fasts, and no doubt this fact will help us to understand how the sea-bird rides out long storms at sea, when the weather conditions are such that feeding may be impossible and the bird's energies may have to be directed entirely to fighting the storm.

The incubation period of the shearwater we found to be a record for a British breeding bird—fifty to fifty-four days. One parent remained in the burrow by day to brood the downy chick for the first week of its existence; but afterwards the chick was only visited by night. When the moon was bright at night, the same thing happened as during incubation—the burrow was not visited at all. The young chick thus early had its first lesson in fasting. However, it was fat from the day of its birth, and showed no perceptible sign of going back during the occasional enforced fasts; in fact

* From a Friday evening discourse delivered at the Royal Institution on November 18.

it seemed simply to sleep and, so to speak, consolidate the position already gained. At any rate, this programme of cramming interspersed with an occasional fast results in the chick becoming enormously fat by the time it is sixty days old. To our surprise, we now found that the parents deserted the chick. They had spent sixty days gathering fish for it and many nights of feeding it with the result of that gathering, from a supply of semi-digested food stored in the parental crop. Now suddenly and completely they gave all this up. They went off to sea and certainly would not appear on the Island again until the following spring. We can surmise, if we like, that the physiological state immediately preceding the autumn moult has something to do with this, to us, rather unnatural desertion of the tender nestling. Yet if it seems unnatural, it is at least not improvident. At this age the chick was so fat that it could scarcely waddle to the sea. If it did so and plunged over the cliffs it would drop and go to pieces on the rocks below.

But after nearly a fortnight of fasting, the fledgling is fully feathered and has very little down visible. It takes off for the sea at night, blundering along on all fours, using wings and legs and beak to scramble over rough ground, for it cannot fly yet. When it reaches the cliffs, it is now light enough to flap down on a long plane and so avoid the rocks below.

Once in the sea the young bird is safe. We have taken shearwaters at this stage and put them in the sea by day. How thirsty they were—I wonder if thirst may not be for them an important factor in drawing them to the sea, the sound of which they must hear before they leave the nest. At any rate, their first action is to drink, then to wash; then suddenly they discover that they can dive. They half-open their wings so that the quills remain partly spread, like a half-opened fan, and with these strong paddles they swim under water with the agility of penguins. They come up for air, and dive again, and so gradually work off to sea, apparently making haste to leave behind the land, of which they have perhaps unpleasant memories of hunger and thirst.

Although we have ringed these young birds, for the time being we have lost them as individuals. But not for long. Recoveries at sea of some of these ringed birds prove that the shearwater has a winter haunt as far south as the Bay of Biscay.

We find that the old breeding birds return faithfully to their nesting burrows early in the spring, and ringing proves that the same individuals pair for another season, probably for life. The breeding bird has built up an association of memories—I scarcely like to call them visual

memories in view of the fact that some of the most important events take place in the pitch blackness of the burrow—which lead it back to the same burrow. It must lose contact with its mate at times at sea in winter, possibly altogether. I do not know. But at least the nest is the focal point, the well-remembered place of meeting, and, allowing for frequent gaps caused by death, we have proved by means of ringing that the shearwater pairs for life.

You may ask, what about the young bird? Does it, too, in succeeding years return to the nesting burrows in one of which it ~~was~~ reared? So far we have not recovered a young bird in the immediate neighbourhood of its birthplace. But it is obvious that in order to keep up the numerical strength of the species a great many young birds must return to breed on the island. It is interesting to speculate as to whether they are guided to the island in the spring by the movements of the adults or by memories of fledging days. Possibly both these factors operate, and the young bird gradually builds a fresh association of memories during preliminary visits to the island. It discovers an empty crevice or hole one night and finds a mate, or more properly I should say a sweetheart, and plays at housekeeping. Next year it will return to this spot, search for or dig a more suitable hole, and start a home in earnest.

To return to more definite information. At present we have adult shearwaters under observation which bred with us for three and four and five years running, and there are two individuals which have bred seven years running. Allowing that the shearwater does not breed until nearly two years old, we thus have individuals five, six, seven and nine years old. So that in time we may well be able to work out the average duration of life of this species.

We have conducted some experiments with ringed sea-birds in an attempt to learn something more of their reputed homing power. An adult shearwater was taken from its egg on Skokholm and released at Start Point in Devon, which is about 200 miles from the island by the sea-route around Cornwall, or 125 miles overland as the crow flies. When released it flew low over the waves, making for sea. It did not attempt to rise up and strike overland in a bee-line for the island. Yet that bird was back on its egg at Skokholm within ten hours. So that if it continued by the sea-route it must have flown steadily at twenty-two miles per hour. Of course its speed by this sea-route must have been much greater, since a shearwater normally does not travel in a straight line, but has a curving, deviating flight, and probably it paused to drink if not to feed.

Two birds released at Fransham Ponds, Surrey,

performed a similar feat and were back at their nests the following night; but in this case before reaching the sea after release these birds had to cross forty miles of land. But land masses interposed between shearwaters and the sea do not seem to disturb the homing faculty. Shearwaters released inland at Birmingham, Evesham and Manchester, as well as at Limerick in Ireland, have safely homed to Skokholm, though not with the rapidity of the Start Point and Frensham releases. Other birds released in the Firth of Forth and as far north as the Faeroe Islands, and as far south as France and north Spain have also got back to their nests on Skokholm in varying times.

All these homing experiments were within, or (in the case of the inland releases) bounded by, the known sea-range of the species. We needed to go farther afield and see what would happen to birds released outside that range. The farthest distance by sea which we could easily arrange for without transport hardships for the birds (for we wished to be sure they were in good condition for a long flight), was Venice, approximately 3,700 miles from Skokholm via the Adriatic and the Straits of Messina and Gibraltar. Two shearwaters from separate nests were sent, by courtesy of Imperial Airways, to Venice, the distance by air being a little less than one thousand miles. So far as I know the Manx shearwater does not enter the Mediterranean, and therefore is not found in the Adriatic. Certainly ringing has so far proved that our Skokholm birds in their winter wanderings do not go beyond the Bay of Biscay. One of these two shearwaters is an individual of some interest to us, for it has returned to its burrow on Skokholm for five consecutive summers. It had already returned safely from Frensham. Now it returned from Venice in fourteen days. It is impossible to say whether it found its way out through the Straits of Gibraltar, or whether it made a bee-line straight over the Alps, or whether it crossed the backbone of Italy and then over the Pyrenees to the Bay of Biscay. The other shearwater may have returned from Venice in that summer; but we did not catch it until the next spring, when it was back at its usual nest.

These experiments have proved a remarkable homing ability, but we have still nothing but theories to explain it, and the physiological mechanism remains obscure.

We have made similar studies of individuals of other species of sea-birds; the storm-petrel, *Hydrobates pelagicus* (L.), for example, which breeds in numbers in the rock crevices and old farm-walls of Skokholm. In a similar study of individuals it has shown a life-history not unlike that of its cousin, the shearwater: nocturnal on land—a long incubation period of 38–40 days—

and an average fledging period of 61 days. The chick is deserted in the end, and flies off to the sea on its own when sufficiently thinned down from its over-fat nestling stage. The storm-petrel is more nervous and difficult to observe than many sea-birds; but we have individuals on our books that have been breeding four years with us in the same crevice.

Our ringing study of the puffin, *Fratercula arctica grabe* (Brehm), enabled us to discover several new facts: an incubation period of 40 days and a fledging period of 49 days. Also the surprising truth that this bird too is deserted by its parents, although other members of the auk family to which it belongs, the razorbill and the guillemot, feed and accompany their chicks at sea when these leave the rocks where they were hatched. The puffin follows the petrel family in deserting its single chick; but this desertion, as with the petrel family, is a wise provision. The young puffin is often reared in burrows some distance from the edge of the cliffs, and so has a long walk to get to that edge, and during that walk it would be exposed to the attacks of predatory gulls and hawks. The puffin chick is full-grown and very fat when it is deserted by its parents. It certainly needs a fast of a week or so to make it light enough to take off without fear of crashing on the rocks below the cliffs. So the young puffin solves two problems, the problem of its excessive weight, and the problem of the predatory gull, by starving for some days before selecting a dark night for its lonely and unseen but momentous stroll to the cliff edge, where it takes the plunge to that friendly element, the sea.

I have spoken of ringing large numbers, even thousands, of sea-birds, and it may be wondered how it is possible for one person to do this and keep account of so many individual birds from year to year. When I began this study of the individual sea-bird I had only my wife's help, and very valuable this was. But we should scarcely have been able to carry on this work as well as our normal duties had we not received encouragement from outside, an encouragement which we were most grateful to have. In the last few years other students have come along, until a voluntary organization has grown under the name of Skokholm Bird Observatory. It is now so organized as to permit us to endeavour to ring every breeding bird on Skokholm, from a rock-pipit to a gull, and to the gannets of Grassholm. We also catch many migratory birds which use the island as a temporary resting place. For example, we ringed in 1938 more than six thousand birds of sixty-one species. This is a figure comparable with figures achieved by subsidized observatories in foreign countries. In Germany and Italy and the United

States, ornithological work of this nature is recognized officially as having an educational and scientific value, and it is blessed with the practical support of the Government concerned. Here in Britain ornithology outside museums depends entirely on voluntary support. So that the running of an observatory on a remote island is not without its anxieties in more than one direction. Rings at three-farthings each add up to a considerable figure in one year, and there is a very large amount of clerical work in the recording and card-indexing of thousands of individual ringed birds. Nevertheless, this voluntary organization is being carried on for the present, and is about to issue its third modest annual report.

Finally, it may be suggested that catching and handling birds must disturb them unduly. On the contrary, by gentle handling many birds have become so used to us that they are almost tame, as tame, in fact, as wild animals are in nature reserves where they have learned that no harm will come to them from human beings. Indeed if the birds were not reasonably tame, it would be impossible to study them individually. This way of studying birds by ringing them is a good deal better than the old way of studying them by means of the gun and the collecting box. Ringing establishes a new kind of contact, a sort of friendly conspiracy with the living bird.

British Empire Cancer Campaign

THE fifteenth annual report of the British Empire Cancer Campaign was presented at a meeting held at the House of Lords at the end of November. The Duke of Gloucester, as president, announced at the meeting that a new cancer research centre of the Campaign was to be established at the University of Oxford and a grant was voted for the work to be carried on at this new centre. During the last year, £50,000 was expended by the British Empire Cancer Campaign on research mainly in Great Britain. Ten years ago the corresponding annual expenditure was only £20,000.

During the past year a considerable amount of work has been carried out on the biological effects of radiations. Mr. H. Burrows, Dr. W. V. Mayneord and Dr. J. E. Roberts have found that the exposure of inflamed tissue in the groins of rabbits to X-rays (600 r.) produced malignant tumours in eight out of nine rabbits. Dr. J. C. Mottram has examined the effect of combined treatment with the carcinogenic hydrocarbon, 3:4-benzpyrene, and gamma radiation. Doses of 160-1440 r. increase the carcinogenic action of the benzpyrene, while higher doses of radiation inhibit this action. It would therefore appear that for tumour production by radiation there is an optimum dosage. Dr. L. D. Parsons has shown that treatment of mice with X-rays or with a carcinogenic agent both result in the deposition of some iron compound giving a Prussian Blue reaction, in the lymphoid tissue. It seems possible that carcinogenic action may be associated with hæmolysis. Lymph glands of mice bearing sarcomas produced by a carcinogenic compound have grown like sarcomas when transplanted into

other mice. These changes occur in glands quite irrespective of their proximity to the graft, and the microscopic appearances suggest that they are not metastatic.

Research carried out at the Middlesex Hospital has shown that if rats bearing the Jensen rat sarcoma are cured by treatment with X-rays, they are afterwards immune to that tumour. Partially successful attempts to transfer this immunity have been made by injecting the fluid from irradiated tumours. Injection of the fluid from tumours which have received a dose of X-rays which would eventually cause their disappearance gives some resistance to this tumour in other rats. Work from the J. H. Burn Laboratories at Newcastle-on-Tyne on two rat tumours has shown that the Jensen rat sarcoma is much more radio sensitive than the Walker carcinoma. The Walker carcinoma also is more resistant to heat treatment *in vivo*, although the two tumours show little difference when heated *in vitro*. Both types of tumour are killed *in vitro* by heating for one hour at 45° or 3 hours at 43.5°.

Experiment has frequently shown that radiation with split doses is more effective than a single exposure. Fresh experiments on mice with epitheliomata at the Mount Vernon Hospital have again confirmed this. Patients at that hospital are treated by the so-called 'stop and go' method in which the tumours are frequently examined and irradiated only when they are considered to be radio sensitive. The intervals between treatments are often as much as three or five weeks.

Investigations on the cancer viruses have not yet led to the isolation of these as chemical entities, but considerable progress has been made in the purification of the Rous chicken sarcoma virus.

It has been found that incubation with purified trypsin for short periods leads to increased activity of Rous tumour extracts, possibly owing to enzymic destruction of inhibiting substances present in the extracts. One of the difficulties in the problem of purification of this tumour-producing agent is the small amount present in tumours. The particles of the Rous virus are about 90 m μ in diameter, and recent experiments carried out by Prof. J. McIntosh show that the particles of the Shope rabbit papilloma virus are of a similar size.

Interesting results have been obtained by Sir Edward and Lady Mellanby on the dissemination of the Rous sarcoma virus in normal and malignant tissues. They have never been able to propagate a chemically induced tumour by cell-free filtrates. If, however, a fowl with a chemically induced tumour is injected with Rous virus, then cell-free filtrates of the chemically induced tumour may produce Rous sarcomata in other fowls. If cell inocula of this same tumour are grafted into other fowls, tumours resembling the original induced tumour are produced. These experiments show that chemically induced tumours cannot contain a virus with similar properties to the Rous virus. The Rous virus will pass not only to other tumours but also to normal organs, so that the blood and the organs such as liver, spleen, muscle and brain of fowls injected with the Rous sarcoma may all contain large amounts of the cancer-producing agent. The amount of virus in the organs is maximal between the seventh and twentieth days after inoculation with the tumour. If intravenous injections of Rous virus are given to fowls, the virus disappears from the blood and is taken up by the organs of the body, but generally no tumours are produced. The organs contain the virus, but do not develop tumours. If, however, a muscle is injured immediately after intravenous injection of the virus, tumours develop at the site of injury, but if the injury is made before injection, then no tumours are developed.

Research into the chemistry of carcinogenic compounds is a branch of cancer research in which the British contribution is pre-eminent. A large number of carcinogenic hydrocarbons have been discovered, some of which are much more active than coal tar and many of which are derivatives of 1:2-benzanthracene. All the theoretically possible monomethyl derivatives of 1:2-benzanthracene have now been synthesized, and of these compounds the 5-, 9- and 10-substituted compounds have definite carcinogenic action; 3-, 4- and 6-mono-methyl-1:2-benzanthracenes have slight activity. The carcinogenic agent of coal tar, 3:4-benzpyrene, can be considered as a derivative of 1:2-benzanthracene with an additional group

in the 9 position; while methylcholanthrene is another derivative with substituents in the 10-, 5- and 6-positions. A new derivative, 9:10-dimethyl-1:2-benzanthracene, has been found to be the most active cancer-producing compound known, producing tumours in about one half the time required by methylcholanthrene.

Some relationship between chemical structure and carcinogenic action of 1:2-benzanthracene derivatives can therefore be shown. If two groups are present in positions in the benzanthracene nucleus (that is, particularly the 5-, 9- and 10-positions) which favour the development of carcinogenic action, then these groups reinforce each other in increasing cancer-producing activity. This summation of the effect of groups in producing cancer activity is analogous to the summation of different cancer-producing factors. One example of this is the combined action of a carcinogenic compound and X-radiation mentioned above. Treatment with carcinogenic agents often increases the incidence of cancer at some particular site to which the animal is normally susceptible. Thus mice have a natural tendency to cancer of the lung which is increased by treatment with carcinogenic substances. In an experiment reported from St. Bartholomew's Hospital, 1:2:5:6-dibenzanthracene was introduced into the stomachs of mice in an attempt to produce cancer of the alimentary tract. All these mice, which survived six months, developed lung cancer. Old rabbits are liable to uterine cancer, and in an experiment in which 1:2:5:6-dibenzanthracene was administered to rabbits by various routes, no tumours were produced at the site of application. A large number of uterine tumours, however, were found, which suggests that the carcinogenic compound possibly increased the incidence of this form of cancer. The tissues of the rabbits to which the substance was applied appeared to be resistant to tumour formation, for the same treatment in mice, rats or fowls would certainly have produced cancer in a certain proportion of animals. Invertebrate animals are not known to suffer from cancer; in the Leeds laboratory earthworms have been kept in earth containing 3:4-benzpyrene for twenty months without showing any histological changes.

Dr. A. Haddow has continued his investigations on the growth-inhibiting action of carcinogenic and related compounds. When animals with tumours are treated with such substances together with X-rays, a summation of effects is obtained. In many cases, animals treated with a carcinogenic

agent alone showed active regression. There are many references in the report to experiments on the possible treatment of cancer by chemotherapy, and the fact that an effect is sometimes obtained by such treatment suggests that development of this method may occur in the future. E. B

State Aid for Scientific Research in Great Britain

SINCE the Committee on New Industrial Development, appointed by the Economic Advisory Council, issued its report in September 1932, the structure and financing of scientific and industrial research has attracted the continuous attention of scientific workers. Many of those interested in the research association movement were concerned as to the future of those associations when the Million Pound Fund was exhausted, and an article from Mr. H. W. J. Stone, secretary of the Parliamentary Science Committee, which appeared in the *Nineteenth Century* in November 1933, urged the importance of more adequate endowment of research and suggested the allocation of revenue for this purpose from the new tariff revenue. Less specific proposals that the granting of tariffs to an industry should be made conditional upon adequate support of research have from time to time been advanced (cf. *NATURE*, 131, 67; 1933), while the national organization of research was discussed much more recently by Sir Daniel Hall in an article in the *Nineteenth Century* in which he proposed the formation of a Planning Council in place of the Economic Advisory Council, to co-ordinate the planning of research and the work of the Medical Research Council, the Department of Scientific and Industrial Research and the Agricultural Research Council.

Other considerations besides finance have focused attention upon the organization of research, particularly the growing importance of social research, the recognition of the disparity between research effort in the physical sciences and in the social and biological sciences, and the need for some re-orientation of effort. Still more recently, national defence considerations have reinforced the cause for further co-ordination of effort. Prior to its merging in the British Association, the British Science Guild gave some attention to the financing and organization of research, and it may be expected that this same question will receive early attention at meetings of the newly formed Division of the Social and International Relations of Science. Closely associated with the British Science Guild in its consideration of this matter until 1936

was the Association of Scientific Workers. Since then, in collaboration with the Parliamentary Science Committee, the Association of Scientific Workers has continued its interest in the question, and a preliminary draft memorandum on the financing of research was prepared (see *NATURE*, 138, 51; 1936). The final draft of this memorandum was transmitted to the Lord President of the Council in April 1937 and has now been published in the *Scientific Worker*, the November-December number of which is devoted entirely to the finance of research, including with the memorandum, the report to the Lord President of Council of the Advisory Council, together with the reply of the Parliamentary Science Committee and the final report of the Advisory Council giving its reasons for not endorsing the proposals. A memorandum on private enterprise as a factor in industrial research is also included.

The main thesis of the argument is that scientific research should be provided with a regular and increasing income. The present system is criticized chiefly because of the rapidly fluctuating amount of money available for research and the lack of provision for the steady development of scientific research in industry. Stress is also laid upon the adverse effect of the present position upon the personnel and conditions of employment of the scientific staff. Accordingly, it is urged that in financing scientific research the first requirement is that it should provide security for completing work undertaken, and the second that it should make provision for steady and maintained expansion of research.

Pointing out that the ultimate sources of money needed for research are the Government and industry, the Parliamentary Science Committee discusses in its memorandum ways in which both might contribute. The idea that scientific research should be financed from Government sources alone is rejected, and also the method of raising funds by a statutory levy from the several industries concerned. Equally the alternative method of a voluntary levy is regarded as unsatisfactory, because it has "the double disadvantage of

penalizing those firms who contribute as against those who do not and affording an extremely irregular income for scientific research".

The memorandum argues, therefore, that if the principle be accepted that industry should contribute directly to scientific research, a way must be found of converting variable contributions into a fixed income; and the proposals outlined are intended to achieve this by the endowment of research. They are summarized in eleven recommendations, four of which are concerned with the needs, maintenance and development of the existing research associations, particularly with regard to continuity, and are strictly independent of the means taken to raise the funds for necessary research. The remaining seven recommendations outline the scheme for endowment of science.

The first four recommendations propose that the Government contribution to the research institutions and to research associations should take the form of block grants for a period of five to ten years in advance, and that the Department of Scientific and Industrial Research, with the Medical and Agricultural Research Councils, should endeavour to obtain a corresponding guarantee of industrial contributions for a corresponding period. It is also recommended that negotiations should be undertaken by the Department with industries for which research facilities are at present inadequate, with the view of providing a comprehensive system of Government-aided industrial research.

The second group of proposals recommends the establishment of a National Scientific Research Endowment Fund, to which the Exchequer would contribute an annual sum of £3,000,000 (or

£2,000,000-£4,000,000) or 10 per cent of the value of Customs receipts. Part of this sum should be used to defray the Government contribution to scientific research, the accumulated reserve of the Fund being invested and the income used to defray part and ultimately all of the expenditure on scientific research. It is also recommended that the Department of Scientific and Industrial Research should endeavour to secure, from industry and agriculture, contributions to the Fund which, over a number of years, would provide an aggregate equivalent to that provided from Government funds. Control of the Fund and of the payments from it to scientific research would be vested in a Scientific Research Endowment Board, an autonomous authority including representatives of Government departments, industry, agriculture and scientific and medical associations, the universities and the public.

In observations on the scheme, the Committee stresses the need for a rationalization of the present organization and for an attempt to bring all scientific research—State, university and, so far as possible, industrial—into one comprehensive ordered and yet flexible scheme. It is pointed out that the scheme is intended to direct attention to four primary needs which must be met before science in Great Britain can be regarded as making its full contribution to the national welfare: a large income for science; a steady income, not dependent on general economic fluctuations; a greater degree of co-ordination of activities; and the completion and development of its connexion not only with part but also with the whole of industry, agriculture and health.

Obituary Notices

Prof. A. W. Porter, F.R.S.

THE death of Prof. A. W. Porter, which occurred at West Kirby, Cheshire, on January 11, has deprived physical science of the services of one who has played a notable part in the development of physics in Great Britain. His death was not wholly unexpected, for, as the result of a fall experienced during the bitter weather of the winter of 1937-38, a fall in which he suffered serious injuries, his health had declined.

Alfred William Porter was born on November 12, 1868. He took up the study of physics at a later age than is usual and, after a course of study at University College, Liverpool, he migrated to University College, London, whence he graduated in the University of London in 1890. He was a fellow of University College, London, and for many years assistant professor of physics in the College, finally

being appointed to a University chair of physics in 1923, from which chair he retired in 1928, with the title of emeritus professor.

Porter's contributions to physical science were the products of an erudite and highly critical mind. It has been said of Maxwell that he had a vast knowledge of the history of his subject, and could always relate some incident about the most familiar fact which would give to it an added interest. Much the same may be said of Porter, who, moreover, had an innate capacity for the critical discussion and elucidation of delicate points dealing with the fundamentals of the different branches of physical science. He was specially happy in such subjects as osmotic pressure, capillarity, colloidal science, and heat, and many generations of students will look back with gratitude to the help they have obtained from verbal discussion with Porter.

His literary activity was great and varied. The treatise on magnetism and electricity known as Carey Foster and Porter's edition of Joubert-Atkinson was far more than a mere translation of Joubert's work, and reflects, in considerable measure, Porter's skill as a teacher. His articles on surface tension in the fourteenth edition of the "Encyclopædia Britannica" and on thermal expansion in the "Dictionary of Applied Physics", are excellent examples of Porter's massive learning and powers of clear exposition, and his capacity for throwing new light on an old problem is admirably shown in his presidential address to Section A (Mathematical and Physical Sciences) of the British Association at Glasgow in 1928, an address which dealt with the Volta effect and some problems in thermo-electricity.

One of Porter's earlier books, a treatise on elementary mechanics, is less widely known than its merits deserve. It was one of the first elementary books to inculcate sound teaching concerning the nature of mass, and the whole subject is developed by easy stages and by the use of the simplest mathematics to a point at which the reader is introduced to the solution of problems concerning the two-dimensional motion of a rigid body. Porter was also the author of two monographs on thermodynamics and on the method of dimensions, and completed, with a considerable measure of success, the difficult task of bringing out a new and revised edition of Preston's "Theory of Light".

Porter was always at his happiest when handling problems dealing with the manifestations of surface energy, and of late years had occupied himself with the calculation of the form of the capillary surface of revolution, giving special attention to the region in which the ordinary methods of approximation are of little use. In these calculations, he never lost sight of the needs of the experimenter, and his results are of great assistance to those concerned with the determination of capillary constants.

Porter's services to physics on the administrative side were most valuable. For many years he acted as secretary to the University of London Board of Studies in physics; he was one of the founder fellows, and the first honorary secretary, of the Institute of Physics. In this last-named capacity he played no small part in forming and in guiding the policy of the newly formed institution. He was president (1913-14) of the Röntgen Society, and president (1920-22) of the Faraday Society. At the time of his death, he was one of the editors of the *Philosophical Magazine*.

Porter was temperamental, and, like most temperamental men, was apt, on occasion, to take up hurriedly a completely indefensible position—and thoroughly to enjoy defending it. He was all the more lovable on that account, for his mind and outlook were always generous, and it is with real and deep sorrow that his many friends of all ages realize that they have looked their last upon the eyes kindly twinkling behind their gold-rimmed spectacles, and that they can no longer call upon that great store of ordered knowledge that was always so readily placed at their disposal.

A. F.

Prof. T. W. Todd

THE death was announced from Cleveland, Ohio, on December 28, 1938, of Prof. Thomas Wingate Todd, anatomist and anthropologist, at the age of fifty-three years. He was born at Sheffield, England, in 1885, and entered the University of Manchester as a student of medicine, graduating in 1907. His attention was originally devoted to surgery; he became a fellow of the Royal College of Surgeons of England in 1911. His early love for anatomy reasserted itself, and he entered the anatomical department of his university as demonstrator and then as lecturer under Prof. Young and later under Sir Grafton Elliot Smith. His first research was on the relationship of cartilage and bone cells to bone formation. Incidental observations led him to infer that certain changes in the coats of arteries were due to pressure on sympathetic nerves.

In 1912, Todd was invited to the chair of anatomy in the Western Reserve University, Cleveland, Ohio. His colleague in physiology was another British subject, the late Prof. J. J. R. Macleod. He had occupied his chair for twenty-six years at the time of death, and had extended his department to many times its original dimensions. The researches carried out by him were of a threefold nature. When he wished to settle such simple matters as the order in which epiphyses unite with their shafts, the times at which the sutures of the skull close, the changes which the human face undergoes from childhood to adolescence, the changes undergone by the bones of the skeleton from maturity to old age, the manner and extent to which male bones differ from those of women, he discovered that such questions could not be answered because there was nowhere in the world a collection of human skeletons of which the age and sex were known. He set to work and slowly accumulated within his department skeletons of white Americans and of American Negroes, of known age and sex. At the time of his death this standard collection contained more than three thousand skeletons, besides skeletons of mature and immature animals—especially of those which most nearly approach man in structure. Fellow researchers joined him from many parts of the world; paper after paper dealing with age and sex changes as manifested in his collections of human skeleton appeared in the *American Journal of Physical Anthropology*, the *American Journal of Anatomy*, the *Journal of Anatomy* and the *Anatomical Record* during the past twenty years.

During the last twelve years of his life, Todd organized a survey of the growth changes in childhood. With the aid of the Brush Foundation, he obtained opportunities and means of keeping eight hundred children, born in Cleveland to well-off parents, under observation from infancy to full maturity. Four times yearly each child was examined medically and physically and records made—especially X-ray records—of the growth changes in their bones. His aim was to obtain a series of stages which would serve as a standard of the normal for medical men and especially for school medical officers. In

1937, appeared the first volume of his results, under the title of an "Atlas of Skeletal Maturation" (St. Louis, 1937). This first volume contains 75 plates giving X-ray photographs of the human hand, each plate representing a certain stage of normal growth. Subsequent volumes were to deal with the growth of other parts and regions of the human body.

Todd made the alimentary tracts of his students the subject of a systematic X-ray survey, his object being to determine what might be the normal dispatch of a bismuth meal in healthy young men, and the extent to which the normal may be departed from within the range of health. His observations were summed up in his Beaumont Lectures of 1930 and published in book form under the title "Behaviour Pattern of the Alimentary Tract".

Todd's object was to lay sure and wide foundations on which other workers might build. He lived and worked to the utmost limit of his bodily and mental strength. He sowed on an immense—an almost unprecedented—scale; it was when he harvested and especially when he came to thresh out and market his grain that his life's endeavour fell short of greatness.

ARTHUR KNECHT.

Mr. S. H. Ray

MR. SIDNEY HERBERT RAY, whose death was recently announced, was born in London on May 28, 1858. In January 1882 he was appointed by the London School Board as assistant master in the Olga Street School, Bethnal Green, a position which he held until his retirement in May 1923. He was twice married, but had no children. He died on January 1, 1939. By unremitting labour, combined with a peculiar gift for languages, he raised himself to an honoured position in linguistic science. A noticeable characteristic of Ray was the absence of self-seeking; he worked under conditions which a less devoted man might well have found impossible. Nothing daunted his enthusiasm, and he became a recognized expert in a neglected field of linguistics.

This is not the place to detail his numerous papers on Papuan, Melanesian and Polynesian languages. On suitable occasions he exposed those who juggled with words in order to support vain theories of origins, for the construction of a language and its phonology were to him of prime importance. His studies of particular languages, however, afforded a basis for those wider surveys in which he gave to students the benefit of his erudition.

In 1892, Ray read a paper on the languages of British New Guinea at the Ninth International Congress of Orientalists, in which he showed definitely that there are languages in New Guinea that differ in vocabulary and grammar from the Melanesian and Polynesian spoken in western Oceania and also from the undoubtedly Melanesian of south-east New Guinea. These non-Melanesian languages he named Papuan as a convenient term for numerous distinct languages with archaic features; about the same time, W. Schmidt made the same deduction for German New Guinea. In 1894, Ray recorded traces of

Papuan languages in various islands of Melanesia. In the same year he demonstrated that the Motu and allied languages of south-east New Guinea were not eastern Polynesian, as had been believed, but were Melanesian. He regarded the languages of the Massim area as originally Papuan upon which have been grafted words and idioms from Melanesian tongues. Their Papuan origin accounts for their diversity, and the Melanesian element, which is common throughout the area, accounts for their partial agreements.

When Ray visited Torres Straits and British New Guinea (Papua) as a member of the Cambridge Anthropological Expedition to Torres Straits in 1898, he for the first time was able to study various languages from the mouths of the natives, and he was untiring in his endeavour to make the most of his opportunities. His assiduity was such that he continually reduced his informants to exhaustion, while he himself remained quite fresh. In 1907 he published, as volume 3 of the Reports, a monumental work on the languages of New Guinea, which extended and confirmed his previous deductions. He proved that the western language of Torres Straits belonged to the same group as those of northern Australia, and that the eastern language was Papuan and allied to certain languages of the extreme west of Papua.

In 1926, Ray published a comparative study of the Melanesian languages, a further proof of his industry and erudition. In Melanesia there is a linguistic sub-stratum which differs from island to island. Upon this was grafted an immigrant Melanesian language which had spread at an early date from Indonesia and through its simpler grammar and facility of expression obscured the radical differences of the older languages. Later there were colonists from Indonesia who settled mainly on some of the smaller islands and introduced a pidgin-tongue. The words can only rarely be referred to any one original Indonesian language and they form only a small proportion of the vocabulary of any single language. The linguistic diversity in parts of Melanesia suggests that the Melanesian languages were originally variant stocks and that their apparent uniformity has been brought about by the influx of Indonesian words and idioms. This was the first of a projected series of studies, but the expense of their publication prevented the appearance of further volumes. In more favourable circumstances, Ray could have enriched linguistic science to a much greater extent; we can only marvel that, handicapped as he was, he accomplished so much work that will have a lasting value.

A. C. HADDON.

Prof. E. H. Hall

PROF. EDWIN HERBERT HALL, emeritus professor of physics in Harvard University, whose death occurred on November 20, devoted most of his life to the study and investigation of electric conduction. He will doubtless be most remembered by the Hall effect which he discovered in 1878. This effect is the production of an electromotive force when an electric

current flows across the lines of force of a magnetic field. This electromotive force is perpendicular both to the magnetic field and to the electric current or, speaking more generally, it is proportional to the vector product of the last two quantities. Other aspects of electrical conduction to which Hall made contributions include the Thomson effect in soft iron, thermo-electric heterogeneity in different metals, the theory of thermo-electric action and of thermal conduction in metals and the relations of the four transverse effects of the magnetic field (the Hall effect was the first of these to be discovered). His keen interest in this field was maintained to the end of his life. In fact, a book entitled "A Dual Theory of Conduction in Metals", in which he summarises his considered views on the subject, has recently appeared.

Hall was born at Gorham, Maine, on November 7, 1855, and educated at Bowdoin College and Johns Hopkins University. Practically the whole of his working life was spent in the service of Harvard University, in which he joined the Physics Department as an instructor in 1881, became professor in 1895 and emeritus professor in 1921. He attended the Solvay Conference at Brussels on the Conductivity of Metals and Related Problems in 1924 and the Volta Memorial Congress at Como in 1927. He was a member of the National Academy of Sciences, American Association (vice-president in 1904),

American Physical Society (member of Council 1908-9), American Academy of Sciences, and corresponding member of the British Association.

Hall's contributions to physics were not confined to the various aspects of electrical conduction. Among the other subjects he wrote of we find the changes in temperature of the walls of steam engine cylinders, the thermal conductivity of nickel and iron, the deflection of falling bodies and the air resistance to falling inch-spheres. Some of this suggests an interest in engineering as well as in pure physics. He was also the author of several text-books of physics of varying scope.

Hall was a kindly man and a pleasant companion. He was interested in a great variety of matters about which he could speak in an attractive and sometimes humorous way. He kept his interests alive until the end, and his loss will be felt by a wide circle.

O. W. R.

We regret to announce the following deaths:

Dr. Calvin B. Bridges, known for his work on genetics at Columbia University and the California Institute of Technology, on December 27, aged forty-nine years.

Prof. H. H. Woollard, F.R.S., professor of anatomy in University College, London, on January 18, aged forty-nine years.

News and Views

Scientific and Other Services in War Time

FROM time to time in the columns of NATURE, reference has been made to the need for full consideration of the part that men of science can take should Great Britain be unhappily involved in a major war. The Association of Scientific Workers has recently had the subject under consideration (see NATURE, Jan. 21, p. 110) and has put forward proposals the fundamental principles of which will, we believe, meet with general approval. A sign that the Government was giving attention to this aspect of national defence was anxiously awaited. The appointment of an advisory council by the Minister of Labour to advise him on the utilization in war time in Government departments or elsewhere of persons with scientific, technical, professional and higher administrative qualifications would appear to be the answer. The representation accorded on the council to scientific interests will not satisfy everyone, but it must be admitted that it is substantial. Sir Walter Moberly has been appointed chairman of the council, and the following have accepted appointment as members: Sir Charles Bressley, Dr. E. J. Butler, Sir Eustace H. Tennyson d'Eyncourt, Mr. S. B. Donkin, Dr. H. L. Eason, Mr. A. H. R. Fedden, Dr. A. P. M. Fleming, Dr. G. S. Gordon, Dr. H. J. Gough, Sir Hector Hetherington, Prof. A. V. Hill, Viscount

Leverhulme, Miss Hilda Martindale, Sir Edward Mellanby, Mr. J. S. Nicholson, Mr. Charles J. G. Palmour, Mr. H. Parker, Sir Robert Pickard, Dr. D. R. Pye, Mr. David E. Roberts, Mr. Basil Sanderson, Mr. T. E. Scott, Sir Frank Smith, Rear-Admiral H. G. Thursfield, Mr. R. S. Wood. The secretary to the Council is Miss B. M. Power, of the National Service Department of the Ministry of Labour, Montagu House, Whitehall, S.W.1.

Dr. Lev T. Berg

ICHTHYOLOGISTS throughout the world will be interested to learn that Dr. Lev Semenovitch Berg, of Leningrad, has recently completed forty years work upon the fishes of his native country. One of his earliest papers, entitled "Ueber Theilung und Bildung des Parablastes bei *Rosa lucius*", was published early in 1899, and from that time onwards a veritable stream of valuable contributions, mainly of a taxonomic nature, has flowed from his pen, and more than one hundred papers bearing his name have appeared in scientific journals throughout the world. Always a patient and careful worker, Dr. Berg has come to be regarded as the foremost authority upon the freshwater fishes of the U.S.S.R., and is a recognized authority upon problems concerning the geographical distribution of fishes. His imposing

work on the freshwater fishes of the U.S.S.R. and neighbouring countries; a third edition of which appeared in 1932-33, will long remain a standard work, invaluable to all students of Palaeolithic fishes. Dr. Berg, who was born in 1876, is still actively engaged in his work, and his many friends and co-workers will wish him many more years of fruitful labour in ichthyology.

Mr. S. Hazzledine Warren

There is a special propriety in the award by the Geological Society of the Prestwich Medal to Mr. S. Hazzledine Warren. The ground of the award, as officially stated, is "in recognition of his researches on the geology and archaeology of East Anglia, particularly in the Lea Valley"; but without detracting in any degree from the value and importance of his original researches and discoveries in this area, it is placed to his credit by archaeologists that his severely critical attitude of mind on every point of evidence bearing on the antiquity, character, and condition of flint implements, and the natural or artificial origin of their fractures, has conduced to sanity in that study of the earliest evidence of man's handiwork, with which the name of Sir Joseph Prestwich has been associated from the earliest days when the discovery of 'eoliths' was first proclaimed. Throughout the whole of his long and distinguished career as a prehistoric archaeologist, Mr. Warren has devoted himself indefatigably to the close scientific examination of such questions as patination, modes of fracture under varying conditions, and other matters depending upon the physical properties of flint, with the view of determining their evidential value as clues in the technology of antiquity; and if he has not always been able to go all the way with his fellow workers, it has been recognized that his conservatism has always advanced knowledge in a real sense and not retarded it. Of Mr. Warren's investigations in the field, posterity will perhaps be most indebted to him for his discovery of the Graig Lwyd factory site, significant for the light it throws on prehistoric economics, and his exploration of the Clactonian industry, which has had so profound an effect on all subsequent study of palaeolithic cultures.

Pre-Crag Implements

A COMMUNICATION has been issued by Mr. J. Reid Moir recapitulating his arguments rebutting the criticisms of his claim for the human origin of the pre-Crag 'implements' discovered in, or derivative from, Pliocene deposits in East Anglia. It has been argued from their physical condition and the high angle of flaking that not only were these flaked flints produced by natural forces, but also that in actual fact they are such as could not have been produced, or if produced, used for their supposed purpose, by man. This, it is claimed, has been shown by experiment. To this Mr. Reid Moir replies, pointing out that the flaking of certain, and especially the older classes of pre-Crag implement could not have been produced by the forces responsible for the striations they exhibit, as these score a post-flaking patination;

while the argument from the steepness of the angle of flaking—apparent in some instances only—and the inability of the modern critic to reproduce typical specimens applies equally to certain types of palaeolithic implement, of which the authenticity is unquestionable. It has, however, been found possible to imitate high angle flaking experimentally, and the product is also a practicable tool for working wood and bone. Mr. Reid Moir classifies pre-Crag implements into five groups, which differ in age and in character of flaking. "Is it to be supposed," he pertinently asks, "that nature varied her methods of flaking flints five times in the Pliocene epoch?" Finally, as the result of many years' study devoted to the examination of later deposits, he asserts that never has he discovered a flint fashioned *in situ* which bears any resemblance to a pre-Crag implement, as might be expected were such flaking attributable to natural forces. At the same time it is to be remembered, he points out, that rostro-carinates have now been found in many parts of the world from Palestine to Java, where glacial conditions and solifluxion could not have operated to produce them.

Social Relations of Science

CORRESPONDENCE has passed between the British Association and the Parliamentary Science Committee concerning the possibility of a working liaison between the Association's new division for the Social and International Relations of Science and the Parliamentary Science Committee. At a recent meeting of the latter body it was decided to invite Sir Richard Gregory, in his capacity as chairman of committee of the new division, to accept co-option to the Executive Committee of the Parliamentary Science Committee, and this invitation has now been accepted by Sir Richard. Normally the Parliamentary Science Committee confines co-option to its executive to members of one of the Houses of Parliament. It was felt, however, that in this instance it was particularly desirable to make an exception in favour of the chairman of this newly formed division of the British Association. It was a fitting compliment on another ground, for, as the erstwhile chairman of the British Science Guild (now merged in the British Association), Sir Richard was intimately associated with the formation of the Parliamentary Science Committee. Indeed, had it not been for other preoccupations at the time, he would have been a member of the Committee from its inception.

Survey of Nyasaland Food Resources

A COMPREHENSIVE nutritional survey, under the leadership of Dr. B. S. Platt, the first of its kind to be undertaken in the British Colonial Empire, is now being carried out in Nyasaland with the object of studying the actual and potential food resources of three contrasting areas. This survey is the outcome of a recommendation made by the Committee of the Economic Advisory Council on Nutrition in the Colonial Empire. Dr. B. S. Platt has been appointed to the staff of the Medical Research Council for five years to organize and co-ordinate, with the assistance

of a small central staff, nutritional surveys throughout the Colonial Empire. The Nyasaland party, which is being financed jointly by the Medical Research Council and the Colonial Development Fund, actually arrived in Nyasaland some months ago. An anthropologist under the auspices of the International Institute of African Languages and Cultures is working with the party. The party is now being joined by Dr. O. K. Ricardo and by Dr. E. Trewavas of the British Museum (Natural History), who will undertake a survey of the fishery resources of Lake Nyasa; and also by Dr. G. A. C. Herklots, reader in biology to the University of Hong-Kong, who has been seconded for eight months to assist with the economic work. It is hoped that the surveys will produce valuable results, on one hand by increasing existing knowledge of the relation between nutrition and ill-health, and on the other hand by suggesting means whereby improvements in nutrition may be effected. It is also interesting to note that the present investigation in Nyasaland is the sort of scheme which Lord Hailey had in mind when advocating, in his recently published *African Survey*, that scientific research should form an essential basis of policy in Africa.

New Broadcasting System

According to a recent report by the New York Correspondent of *The Times*, a new type of wireless transmission and reception will be used in an experimental station now being erected at Columbia University by Major E. H. Armstrong, professor of electrical engineering in the University, and inventor of the now well-known supersonic-heterodyne receiver. The station will use the frequency-modulation system of transmission, as distinct from the amplitude-modulation system at present used by all broadcasting stations. In the former method, the frequency of the emitted carrier wave is varied by the speech and music modulation; whereas in the methods so far employed, the frequency of the carrier wave remains constant and its amplitude is varied by the applied audio-frequencies. The principles of frequency-modulation have been known since the earliest days of radio-telephony, but it has remained for Prof. Armstrong to demonstrate how these may be brought into practical use with modern valves and circuit arrangements. Among the advantages claimed for the new system are that it effects a considerable reduction of interference in radio reception, and that a much larger number of broadcasting channels will become available in any given wave-length band. Against these, however, is the serious disadvantage that special receivers are necessary for frequency-modulated transmissions, and this factor is likely to involve serious delay in the introduction of the new system into modern broadcasting technique. The first transmitting station on the new system will be at Alpine, New Jersey, opposite New York City, and it has a licence to broadcast on a frequency of 40 megacycles per second (wave-length 7.5 metres). It is also understood that suitable receivers are already being manufactured, so that the result of this practical experiment will be awaited with interest.

North Rona: A North Atlantic Island

At the Friday evening discourse at the Royal Institution on January 20, Dr. F. Fraser Darling described the island of North Rona. It is Britain's loneliest island; it lies forty-five miles north-west of Cape Wrath and north-east of the Butt of Lewis and is less than half a square mile in area. The island consists of Hebridean gneiss, but being free of peat and covered with a thin layer of soil, it differs radically from Lewis in its vegetative covering, which is of grass, quite free from heather. St. Ronan is reputed to be the first human inhabitant of Rona in the eighth century A.D. He built a cell almost underground, and much of the original building is still present. A chapel was built somewhat later contiguous with the cell and at its western end. Dr. and Mrs. Fraser Darling have excavated the accumulated stone and earth from the chapel and cell, disclosing the altar supports of masonry in the chapel, the rammed clay floor, the doorway into the cell, the original stone paving of the earlier building and the altar of masonry in the cell. Many quern stones and two fragments of stone vessels have been found. The wild life of Rona is of exceptional interest. There is an immense summer population of guillemots, razorbills, puffins, fulmar petrels, kittiwakes and great black-backed gulls. The storm petrel is also numerous, and Rona is one of the three British stations where Leach's fork-tailed petrel breeds. Rona is the headquarters of the Atlantic grey seal in Scottish waters, and a study of the social behaviour of this animal in the months it is ashore for breeding was the main purpose of Dr. Fraser Darling's expedition. Although this seal cannot dispense with the land for reproduction, this annual association with the land is a time of great danger. The social system is finely adapted to reducing the danger, and so are the animal's metabolic processes. The maiden cows and immature stock, for example, do not come ashore on the main mass of the island at the breeding season, but remain on skerries constantly ringed with surf. The calves feed from their mothers intensively for three weeks and are then weaned and left to find the sea for themselves. As the gestation period is 11½ months, mating takes place while the mothers are ashore with their calves.

Royal Meteorological Society

At the annual general meeting of the Royal Meteorological Society held on January 18, Dr. B. A. Keen, the president, referred to the Council's activities in pressing for the installation of meteorological institutes in Great Britain, in order that urgently needed facilities, such as were available in many other countries, might be provided for research in meteorology in this country. The matter was also raised later in the evening, on the occasion of the award of the Buchan Prize to Dr. E. W. Hewson. Dr. Hewson, who is a Canadian and has recently been appointed to the Canadian Meteorological Service, was not able to be present to receive the prize, but in a letter which was read to the meeting he expressed his sense of indebtedness to the Beit Trustees and to the Royal Society of Canada for

the grants which had enabled him to carry out research in meteorology at the Imperial College of Science and Technology in London for three years; and he stressed the great benefit which could be conferred on science by the endowment of scholarships in meteorology which would permit post-graduate students to study meteorology in Great Britain. Dr. Keen's presidential address dealt with the subject of "What happens to the Rain?" An annual rainfall of 30 in. means that 3,000 tons of water fall on an acre of land. In the course of the year this all disappears, by run-off, evaporation, transpiration through vegetation, and by downward percolation. The relative importance of these factors in British and overseas conditions was discussed. It is only in recent years that the true picture of the movement of water in the soil has been built up. In consequence, some of the traditional practices need revision, while others now have a different explanation. The new work has also clarified some of the concepts used in hydrology.

Opening of Griffith Institute of Archaeology, Oxford

THE Griffith Institute of Archaeology, an extension of the Ashmolean Museum of the University of Oxford made possible by the generous benefaction of the late Prof. F. Ll. and Mrs. Griffith, was declared open on January 21 by Sir Frederic Kenyon in the presence of the Vice-Chancellor, Mr. G. S. Gordon, president of Magdalen College, and a large assembly of distinguished guests. Sir Frederic, speaking as an old friend of Prof. and Mrs. Griffith, said that never had he known a man more single-minded and more tolerant of the work of others than Prof. Griffith. The Griffith Institute would fill one of the great gaps in the equipment of the archaeologist. The Vice-Chancellor and Mr. E. T. Leeds, keeper of the Ashmolean, also paid generous tribute to the memory and work of Mr. and Mrs. Griffith. The building in which the Institute is housed is of four floors, erected to the design of Mr. E. Stanley Hall. Three floors are allotted to Egyptology and Assyriology, while the ground-floor is given up to other activities of the Museum. The greater part of the Griffith library is housed in the Institute, and accommodation is provided for the professor of Egyptology and the reader in Assyriology. Space is available for the compilation of the topographical bibliography of Egyptian hieroglyphic texts and other research work, while a large store-room will provide for the Egypt Exploration Society's collection of papyri, which has been transferred from Queen's College, and the collections of ostraka and other material used for purposes of teaching. The University's collection of cuneiform tablets will be arranged in the rooms devoted to Assyriology.

Proposed Museum of Romano-British Archaeology

LORD EUSTACE PERCY, Rector of the Newcastle Division of the University of Durham, has issued an appeal for funds for the erection of a Museum of Romano-British Archaeology, devoted to the area of the Roman Wall at Newcastle-on-Tyne, in connexion with the University of Durham. The proposal arises

out of a recommendation of the Standing Commission on Museums and Galleries made two years ago, which had in view the need both of facilities for study of the area of the Wall and also of the requirements of the magnificent collections of Romano-British antiquities belonging to the Society of Antiquaries of Newcastle, the main source of information concerning the Roman frontier in Britain and settlements adjacent, which have been brought together in the course of the last hundred years, and are now somewhat inadequately housed in the medieval Black Gate of the Castle. The Society has generously expressed its willingness to place its collections at the disposal of the University for this purpose, subject to certain conditions. Although the erection of such a museum had been contemplated in the projected building scheme of the University, it had been set aside for the moment in view of more urgent needs; but it has now been brought within the range of practicable proposals by the offer of a grant of £5,000 from the University Grants Committee, provided the further sum required to make up the total estimated expenditure of £20,000 is raised within a period of two years. The Museum will not be confined to Romano-British antiquities but will include all relics obtained from the area of the Wall, both prehistoric and of post-Roman date down to the Norman conquest. Subscriptions are being received by Lord Eustace Percy at King's College, Newcastle-on-Tyne, 2.

Testing Electric Meters and Appliances

THE opening of large extensions by the Lancashire Electric Power Co. on January 16 of its department for testing electric meters and electric appliances shows how rapidly this branch of the firm's work is developing. That part of the firm's revenue which depends upon meter registrations now exceeds a million pounds per annum, while the number of meters issued has almost quadrupled during the last nine years. A great deal of the extra work done is in connexion with household appliances, offered by the firm on hire and hire-purchase terms. These are installed and maintained by the testing department. The number of domestic appliances connected, such as cookers, water heaters, fires, kettles, etc. increased in number from 400 in 1930 to 10,700 in 1934 and to 38,000 last year. In the last two years, 2,000 thermostatically controlled cookers have been issued to customers. Nearly all the domestic consumers pay on a two-part tariff with a power charge of 0.5-1d. per unit. All meters are tested when removed from service, after which they are reconditioned and certified. A small cleaning room is provided for exceptionally dirty meters, the equipment of which includes a powerful blower and an extractor fan. At the opening ceremony, it was stated that an electricity meter is not only one of the cheapest but also one of the most accurate things the firm has on the market. Since 1936, all cookers offered by the firm have had automatically controlled ovens. Their thermostats are checked for consistency and the enamel is tested for durability. Tests include temperature measurements every

minute at five different points in the oven; if satisfactory, these tests are repeated with food in the oven. The L.E.P. Co.'s experience is that the most critical practical test of an oven is the baking of plate pies, and the next most critical the baking of bread.

Thermionic Valves as Measuring Instruments

THE thermionic valve has long been recognized as a useful tool in many branches of science and engineering; but few, with the exception of experimenters, have realized that it can be usefully applied for measurement purposes. Until quite recently, engineers have regarded the valve as being rather an unknown factor and so have been reluctant to rely on it when precision measurements are required. In a paper presented to the Institution of Electrical Engineers on January 6, by Dr. E. G. James, G. R. Polgreen and G. W. Warren, the principles are outlined of various kinds of valves for the measurement of alternating voltages (including 'slide-back', peak, grid-leak and anode-bend voltmeters) and of voltmeters and electrometers for direct voltages. Methods of measuring very small values of current and power are described. Although the uniformity existing between the characteristics of valves of the same type is not quite perfect, the modern valve gives a very stable performance during its life, more particularly under the operating conditions imposed in measuring devices. Of all valve-measuring devices, the valve voltmeter probably is the most widely used instrument, especially for high-frequency measurements. It is sensitive and it can be designed to absorb negligible power from the source. In normal instrument practice, current is measured either by its magnetic or by its heating effect, and voltage is measured by measuring the current through a known resistance. In the case of instruments employing valves, the converse procedure is adopted. Voltage is measured by its controlling action on the electron current in the valve, while current may be determined by measuring the voltage produced across a known resistance. A simple and inexpensive valve voltmeter can be made to operate from pocket lamp batteries. It makes a useful self-contained instrument with the general advantage of very high impedance and wide frequency range. The paper is a communication from the Research and Engineering staffs of the General Electric Co., Ltd., the M.O. Valve Co., Ltd., at Wembley and the works of the Salford Instrument Co.

Progress of Medical Psychology

IN an address at a public luncheon arranged by the National Institute of Industrial Psychology on January 18, Dr. J. R. Reese, medical director of the Tavistock Clinic, said that this century has seen very great progress in both the science and the art of psychological medicine. Moreover, in the treatment of neurosis and nervous breakdown and in medicine as a whole, the introduction of the principles of medical psychology in the last few years has brought about a greater change than anything else in medicine. In the basic understanding of the processes

of mental disease, much is owed of course to Freud and his followers, but the work of Jung, McDougall, Adler, Rivers and Hadfield—to mention only a few—has been of an outstanding quality. The medical student can now be taught to understand the human beings with whom he has to deal without the use of any technical jargon and without any exclusive reference to a particular school of thought in psychology. In the actual treatment of the neuroses we are making steady advance. There is evidence from the careful follow-up work which has been done, first of all at the Tavistock Clinic and then at the Cassel Hospital at Penrhurst, that approximately 50 per cent of the patients treated, irrespective of the particular method, seem to be permanently relieved and socially adjusted. That is a very satisfactory figure in comparison with the figures for other diseases. More important perhaps than the provision of treatment for the definite neuroses is the fact that through recent research we are coming to realize that many of the illnesses which have always been supposed to be mainly physical, have in fact a very large emotional factor in their causation. Psychological medicine is now coming into its own place in the system of medicine and is showing itself to have the closest possible relation to the problems of general medicine. The General Medical Council has now insisted that medical psychology should become part of the regular training of every medical student.

Flora's League

BOTANISTS, nature-lovers and those who are concerned for the conservation of the native British flora will be interested to know that it has been decided to continue the activities of Flora's League, the national society for the preservation of wild flowers, trees and ferns, as a memorial to its founder, the late Sir Maurice Abbot-Anderson. Sir Maurice, a distinguished physician, founded the society in 1925 and was its president up to his death, when it had a following of more than twenty thousand members and a wide influence through the public and school lectures it organized as propaganda for the preservation of the British flora from vandalism and unscientific collecting. Lady Abbot-Anderson has undertaken to carry on her husband's work as president of the League, which is closely associated with the Council for the Preservation of Rural England, the office of which it shares, and an appeal is being made for a fund to continue this work. In a statement on its policy, the League clearly refutes any suggestion of mere sentimentality or crankiness in its methods, for it points out: "There are inevitable economic influences at work which mitigate against the preservation of our wild flora, and with which we cannot quarrel. Building, road-making, drainage, quarrying and the like, must, in the ordinary course of things, proceed. Methods of transport also are more easily available, and bring enormous enjoyment, as well as increased health, to the population". A by-law against the uprooting of any wild plants from roadsides and places to which the public has access, without authoritative

permission or a special permit for scientific purposes, is one of the chief aims of the League, and this has already been adopted by fifty-two counties and sub-counties in England and Wales. From 1925, the whole of the expenses were met by the founder.

Mathematical Films

IN connexion with the note in *NATURE* of December 31, p. 1151, Mr. Stefan Bergmann writes to point out how films might be used to illustrate the theory of functions of two complex variables. Each complex variable may be represented as a point in a plane, requiring two dimensions, so two such variables require four dimensions. We may obtain these by taking three dimensions in space and one in time, in fact by making a film showing a solid body the dimensions of which vary with the time. Full details were given by Mr. Bergmann some years ago (*J. Deutsch. Mathematiker Verein.*, 42, 238; 1932-33), but so far as we are aware no such films appear in current lists of those available for sale or hire.

Nutrition and Local Government

THE Children's Minimum Council, 72 Horseferry Road, London, S.W.1, has issued a pamphlet entitled 'Nutrition and Local Government—What Your Local Authority Can Do' (by Marjorie E. Green. Price 3d.). Although changes in legislation are still needed to ensure that no child shall suffer from malnutrition through the poverty of its parents, there are two Acts of Parliament, the Public Health Act of 1936 and the Education Act of 1921, which enable local authorities to provide supplementary nourishment, and this pamphlet sets out clearly what each local authority can do in its own area to solve this problem of child malnutrition.

Rheumatism Research in Naval Training Centres

THE Empire Rheumatism Council, in co-operation with the Admiralty, has set up a research foundation to investigate rheumatic disease in the training establishments of the Royal Navy. The research advisory committee has appointed a sub-committee consisting of Lord Horder, Sir William Willcox, Prof. George Hadfield, Dr. Mervyn Gordon and Dr. W. S. C. Copeman to supervise the work. Dr. C. A. Green, of the Bacteriological Department of the University of Edinburgh, is to take direct charge of the Foundation, and the Sir Halley Stewart Trust has appointed him to a research fellowship for three years for this task.

National Nutrition Conference

THE British Medical Association has decided to call a national conference on nutrition in its wider aspects—that is, in relation to national, including agricultural, policy—which will last three days, the dates provisionally selected being April 27-29. In addition to medical men, the conference will be representative of agricultural producers, home and over-seas, as well as of industry and education. The conference will take as its starting-point the recognized food needs of the individual, if health is

to be maintained. Questions to be considered include: How far are these needs satisfied in Great Britain at the present time? What increases are required in the production of particular foodstuffs, either at home or in the Empire, to fill the gap? How can the necessary increases in consumption be best secured—through a system of family allowances; education, including propaganda; or otherwise?

Micro-Methods for Medical Practitioners and Biologists

IN conjunction with the Institute of Scientific Microscopy and Applied Optics of the University of Jena, Messrs. Carl Zeiss, Jena, are organising a course of microscopy, microphotography, micro-cinematography, micromanipulation, luminescence microscopy, also absolute colorimetry, interferometry and spectral analysis, with particular reference to their significance in medicine and biology, to be held in Jena during March 27-April 1. During the lectures provided in the programme there will be talks by eminent authorities on optical methods. Of particular note is the fact that members will be offered the opportunity of widening their experience in the use of the apparatus and above all of trying out in practice the methods referred to during the lectures. Demonstrators and specialists will be available to answer all questions arising during the practical work in the laboratory. Further particulars and detailed programme can be obtained, in England, from Carl Zeiss (London), Ltd., Mortimer House, Mortimer Street, W.1.

New Comet and Super-nova

A TELEGRAM from Copenhagen reports that Peltier, at Delphos, Ohio, discovered a comet on Jan. 20.000 U.T., its approximate position being R.A. 21^h 20.0^m, Dec. + 28° 0', and its magnitude 8. A later telegram states that Beljawsky saw the comet several hours earlier and found that its daily motion was +5^m 48^s in R.A. and -0° 13' in declination. He gave the magnitude as 8 and estimated the tail to be about 1°. Other observations must have been available to Karstedt, who has computed the orbit and ephemeris given below; as the observations are very rough, the orbit cannot be regarded as more than provisional.

T	1938 Dec. 30.0 U.T.

Zwicky reports a super-nova, mag. 17 on January 14, 12.5 on January 20. It is 0.6' north-west of the nucleus of N.G.C. 4636.

The Night Sky in February

THE moon is full on February 4 at 7.9^h U.T. and new on February 19 at 8.5^h. Lunar conjunctions with the planets occur as follows: with Mars on February 12 at 13^h; with Venus on February 15 at 3^h; with

Jupiter on February 20 at 12^h and with Saturn on February 23 at 6^h. Jupiter, which has been a conspicuous object in the evening skies for some months, is now approaching conjunction with the sun, and in the middle of the month sets at about 18½^h. Mercury and Jupiter are close to each other on February 26. Saturn is an evening star in Pisces; in mid-February the planet sets at about 21¼^h. Venus is the bright morning star rising before 5^h; its stellar magnitude is from -4.0 to -3.9. Mars rises some two hours before Venus, and is 5° north of Antares on February 12. In mid-February, the constellation of Orion, which focuses attention on the most spectacular region of the whole sky, comes to the southern meridian at about 20^h. North preceding the Pleiades is the variable star, Algol, the light changes of which may be observed about 1½ hours before and after the following times of primary minima: February 9^d 0.1^h, 11^d 21.0^h and 14^d 17.8^h.

Announcements

PROF. G. INGLE FINECH, professor of applied physical chemistry in the Imperial College of Science and Technology, was presented at the Belgium Embassy on January 23 with the order of Commander of the Order of King Leopold II, which has been conferred on him by King Leopold III for services rendered to science in Belgium during his term of office as Fondation Francoqui professor in the University of Brussels during 1937-1938.

PROF. VICTOR F. HESS, formerly director of the Physical Institute of the University of Graz, has been appointed professor of physics in Fordham University, New York, as from November last. His address is: Department of Physics, Fordham University, New York City.

MR. A. S. E. ACKERMANN has been elected an honorary fellow of the Society of Engineers (Inc.) upon relinquishing the secretaryship of the Society, which he has held for thirty-one years.

It is announced that a sale by auction will take place at Stevens Auction Rooms on February 10, at 12.30, of the important collection of scientific instruments, the property of the late Edward Milles Nelson. They include microscopes by Leitz, Powell & Lealand, Swift, and other well-known makes, objectives, eyepieces, and other accessories, chemical balances and weights, a spectroscope, a telescope, drawing instruments; books, etc. Catalogues can be obtained from the Auctioneer, 38 King Street, Covent Garden, W.C.2.

At the annual general meeting of the Royal Meteorological Society held on January 18, the following officers were elected: *President*, Dr. B. A. Keen; *Treasurer*, W. M. Witchell; *Secretaries*, H. W. L. Absalom, W. Dunbar, and E. L. Hawke; *Foreign Secretary*, J. F. Shipley; *Editor*, Sir Gilbert Walker; *New Members of Council*, Lieut.-Commander T. R. Beatty, L. O. W. Bonacina, and G. Manley.

At a meeting of the Chemical Society on January 23, it was announced that Dr. H. J. T. Ellingham is resigning from the office of honorary secretary. The Council of the Society has nominated Prof. G. M. Bennett as honorary secretary and Mr. F. P. Dunn as treasurer, for election at the annual general meeting on March 30. The Council has also accepted with regret the resignations of Prof. F. Challenger and Dr. S. Glasstone from the office of local representative for Leeds and Sheffield respectively, and has invited Dr. J. W. Baker (Leeds) and Sir. A. W. Chapman (Sheffield) to fill these vacancies.

PROF. OTTO LOHWI has been appointed by the Fondation Francoqui as a visiting professor for eight months to a Francoqui chair in the University of Brussels. His address during that time will be: Fondation Universitaire, 11 Rue d'Egmont, Brussels.

PROF. OTTO MEYERHOF, For. Mem. R.S., of the Kaiser Wilhelm-Institut für Medizinische Forschung, Institut für Physiologie, Heidelberg, writes that his address from now on will be Institut de Biologie Physico-Chimique, 13, Rue Pierre Curie, Paris, 5.

DR. ROBERT FEULGEN, professor of physiological chemistry at Giessen, has been elected a member of the German Academy at Halle.

PROF. F. POTRUSKY, of Bonn, has been elected honorary president of the International Academy for Forensic and Social Medicine.

DR. LOUIS MARTIN, director of the Pasteur Institute of Paris, has been elected vice-president of the Paris Académie de Médecine and M. Gaston Louis Ramon, sub-director of the Institute, has been created a Commander of the Legion of Honour for his work on immunization against diphtheria and tetanus and combined inoculations.

On the occasion of the International Water Exhibition and the inauguration of the Albert Canal, the eighteenth session of the Congress, known as the Journées médicales de Bruxelles, will be held at Liège on June 24-28 under the presidency of Prof. Ernest Renaux, member of the Belgian Royal Academy of Medicine. Further information can be obtained from the general secretary, Dr. René Bekkers, 141 rue Belliard, Brussels.

THE Annual Congress of the Ophthalmological Society of the United Kingdom will be held at the Royal Society of Medicine on April 20-22, when the subject for discussion will be the problems of refraction.

THE University of Groningen will commemorate on April 29-30 the one hundred and fiftieth anniversary of the death of Peter Camper, the celebrated physician, anatomist, obstetrician and artist, who was for ten years a professor at the University.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 166.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

The 'Thumb' of the Giant Panda

SOME reference has been made in the daily Press, during the past few days, to the extraordinary grasping power possessed by the giant panda at the London Zoological Gardens. It has been stated that "It is now seen that the fingers are used in conjunction with a thumb on each hand to grasp the bamboo. The thumbs are not tapered like the fingers. They are broad stumps, but they are connected with adductor muscles, by means of which they can be brought into contact with the fingers".

True opposable thumbs, capable of grasping, are possessed only by animals that have never ruined their grasping arboreal hands by using them to support the body weight in terrestrial pronograde progression. The giant panda is apparently a non-arboreal, quadrupedal pronograde, and should it have retained a truly opposable thumb, it would be a very remarkable circumstance: should it have re-developed an opposable thumb (for the purpose of grasping bamboo shoots) from one that had lost its structural basis of opposability, it would have performed a miracle. Not even the giant panda could be expected to reverse structural evolution to the extent of making an opposable, grasping thumb from one in which all the structural adaptations to this functional end had been lost. But the giant panda has done something that is almost equally remarkable. It has developed a new and thoroughly efficient pseudo-thumb. For the 'thumbs' which are 'broad stumps' are not thumbs at all, though they have attained, with great perfection, to their functional role. In addition to the pseudo-thumb, there is a true first digit, followed by four other digits: and the true thumb is in no way differentiated from (but is smaller than) the rest of the digits.

Upon the radial side of the carpus, there is developed in many mammals a sesamoid bone corresponding to the pisiform upon the ulnar side. In the true bears, the radial sesamoid is a small nodular mass; in the giant panda it has been developed into an elongated bone articulating with the scapho-lunar and projecting from the radial side of the hand after the fashion of a true thumb. Moreover, many of these muscles, which in normal mammals are inserted to the first digit, gain their insertion, in the giant panda, into the radial sesamoid, which thus usurps the place of the true thumb and simulates all its movements. The anatomical details of this curious adaptation will form the subject of a communication to the Zoological Society of London, to the authorities of which I am indebted for the opportunity of dissecting the fore-limb of this animal. In the meantime, it seems worth while to record this curious example of adaptation, by which an animal in which the thumb had lost its structural modifications for opposability and general mobility, has created a new and extremely serviceable 'thumb' in response to a

special need in its economy. It would seem that what is commonly known as Dollo's Law of the Irreversibility of Structural Evolution was sufficiently rigid to make the creation of a new mobile thumb an easier matter than the remodelling of one that had lost its original structural adaptation to mobility. But it is surely a very definite triumph that the giant panda has been able to make so perfect a new thumb as to deceive those who have admired the perfection of its grasp.

The Electronic Charge

WE have made modifications in the drop method for measuring the electronic charge, e , which enable a higher degree of accuracy to be obtained.

The method is also convenient for measuring the number of elementary charges, n , which are carried by a drop when it is detached from a volume of oil. Results of such measurements are given below.

The method used is that of H. A. Wilson, modified by (1) the use of a horizontal electric field; (2) recording photographically the motion of the drop.

Following Millikan, to reduce the evaporation of a drop, one of oil is used. The drop moves in air between the vertical plates of a condenser. During the first part of its motion it is acted upon only by its weight; then an electric field, X , is established, and a horizontal force, neX , acts too on the drop. If v is the vertical, and u the horizontal component of its velocity, and if Stokes's law applies, then

$$ne = k\mu^{1/2}v^{1/2}u/X,$$

where $k = 9\pi\sqrt{2}/\sqrt{g(\rho-\sigma)}$, and μ is the viscosity of the air at the temperature of the experiment. This value of e requires correction, according to the method devised by Millikan, to allow for the departure from Stokes's law.

The drops of apiczon and castor oil used have had a diameter, $2a$, of 0.0002-0.0010 cm. They are illuminated by a carbon arc with a dark-ground condenser designed for the purpose. The exposure is 0.0008 sec. at intervals of 1/25 sec. A low-power microscope objective and a fine-grained photographic plate is used. An example of a photograph obtained is reproduced in Fig. 1.

With this method, displacements correct to about 0.00003 cm. can be measured, and if the velocity is 0.3 cm./sec., intervals of time measured are correct to 0.0001 sec. It enables the velocities of drops to be measured which, on account of their large radius, move too quickly for accurate visual observation. For these drops, the correction factor to Stokes's law

$(1 + A/\rho a)$ is more nearly 1 than for smaller drops, and the error in the value of e due to Brownian motion is diminished.

The vertical and horizontal velocities of a drop can be observed, too, with sufficient precision to make possible the verification of the assumptions made in deriving the expression given above. We have in this way detected small errors which have been removed by experimental improvements.

Fig. 1.
PHOTOGRAPH OF DEFLECTED DROPS.

It would be premature to state the value of e which has been obtained in our preliminary measurements, but so far it is slightly lower than that of Millikan. (The increase in his value from 4.77×10^{-10} to 4.8×10^{-10} e.s.u. is made necessary by recent determinations of μ for air.)

Drops of oil formed by detachment from the steel wires of a brush are found to be electrically charged.

Fig. 2.
RELATIONSHIP BETWEEN CHARGE ON AND VOLUME OF OIL DROP. I, APIEZON OIL, SAMPLE A; II, APIEZON OIL, SAMPLE B; III, CASTOR OIL.

The values observed for three oils are shown in Fig. 2, in which n , the average number of electrons per drop, is plotted against the cube of the radius, a^3 . For these three oils n is apparently proportional to a^3 . Drops of castor oil to which more than 1,000 electrons were attached have been photographed. Long-chain molecules of glycerides of ricinoleic acid, $C_{18}H_{33}O_2$, $CH(OH).C_2H_5$; $C_{18}H_{33}O_2$, $COOH$, and of the free

acid are present in castor oil. Presumably a number of these chain molecules are broken in the formation of a drop, thus causing it to be charged.

We are indebted to Mr. T. P. Gill for valuable assistance in the electrical measurements.

The Expanding Universe and the Origin of the Great Nebulae

Prof. G. Gamow and Dr. E. Teller have propounded¹ an interesting view of the genesis of the nebulae, but I doubt if either their arguments or their calculations can survive criticism. In brief, they think that the average density of matter in the present universe is about 10^{-28} ; that matter of this density, spread uniformly as a gas through space, could only condense into the present nebulae if the gas-molecules were at a temperature of "several million degrees, which seems to be very unlikely"; that for condensation to have taken place in the past, inter-nebular distances must have been less than now by a factor of about 1,000. "Since the present average distance between the nebulae is just about 1,000 times larger than their diameters, we conclude . . ." and so on. Their whole cosmogony is based on the supposed equality of these two factors of 1,000. I believe both to be wrongly calculated.

The average inter-nebular distance is about 2,000,000 light-years², but the average diameter of a nebula³ is certainly more than 2,000 light-years. The true ratio here is probably nearer to 100 than to 1,000.

Recent investigations by Sinclair-Smith, Holmberg and others suggest that Hubble's estimate of 10^{-28} for mean density (which was anyhow only given as a lower limit), is emphatically on the low side. The average nebula appears to have a mass of at least 10^{11} suns. This gives a mean density, for nebular matter alone, of 2.5×10^{-28} , which reduces the needed contraction from 1,000:1 to 40:1. But this is not all; in calculating the criterion for the formation of condensations, the authors neglect the gravitational field of all uncondensed matter outside the incipient condensation. My own calculations⁴ indicate that this introduces a further wrong factor of $8\pi^2/9$, or about 9.

When all this is put straight, I find that the present universe, as it now stands, could be formed by the condensation of a gas with a 'thermal' velocity of about 20 km. a second. To obtain this velocity, we need not postulate gas molecules (!) "at temperatures of several million degrees"; we can get it from hydrogen atoms at 19,000° C., or from free electrons at -260° C., or from a mixture of atoms and electrons at any temperature we choose between -260° C. and 19,000° C. The range is so wide that nothing can be ruled out as impossible.

The range of universes which could be formed by gas-condensation would appear, then, to include the actual present universe. If so, we cannot form any estimate of the epoch, or any picture of the manner, in which our universe was formed, from the considerations proposed by Gamow and Teller.

I believe other objections can be brought against their arguments without being hypercritical. For example, in the expanding universe of the theory of relativity, material particles gain kinetic energy during the process of expansion. But this gain must

not be included in the equation of energy; if it is, there is no longer conservation of energy. This makes me think that the authors' arguments about velocity of escape are invalid.

Glaciological Results of the Jungfraujoch Research Party

LAST spring a note was published in NATURE on the aims of our expedition to the Jungfraujoch to study glaciological problems. The working out of our results has now progressed so far that we are able to give a brief account of them.

The main part of the work was concerned with the study of the transition of snow into ice in glaciers, but the results obtained also threw considerable light on the mechanism of glacier flow.

The general scope of the work and results may be outlined as follows:

(1) *Transition of snow into glacier ice.* Specimens of firn and ice were removed from the walls of deep crevasses and artificial shafts in the interior of the glacier. Depths one hundred feet below the surface were explored. The samples were examined in a laboratory which had been excavated in stationary ice at the Jungfraujoch. The temperature of the laboratory remained at about -4°C . throughout the summer. The change in density with depth was determined at various points between the source and firn line of the Great Aletsch Glacier. From these results it was possible to draw a profile of the density distribution in the glacier and to define a transitional plane between firn and glacier ice. Usually the density increase on passing from early firn to glacier ice was found to be a gradual one. However, a transition point between the two could be distinguished at a density of about 0.84, since here the hitherto porous firn becomes impermeable to water by the freezing out of descending melt water and by a slow process of settling. Measurements indicate that the latter process is an important factor in increasing the density.

(2) *Névé temperatures.* By means of thermocouples buried at depths down to 30 m., it was found that the winter cold wave penetrated to about 15 m. depth. Below this depth it was concluded that the whole glacier was at the pressure melting temperature. The heating of the firn in summer is attributed to a downward percolation of melt water from the surface and it was found that the rate of temperature rise depended on the firn structure and its permeability to water.

(3) *Crystallographic studies.* Using the standard methods of optical crystallography, the size, shape and orientation of the crystals and the distribution of the air spaces were studied in thin sections cut from specimens which had been taken from the interior of the glacier. A statistical survey of the orientation of a large number of crystals in these sections gave evidence of the presence or absence of any preferred orientation. Although firn near the surface showed orientation due to growth in a uni-directional cold wave, this orientation was observed to disappear gradually at greater depths by the independent movement of firn grains during glacier flow and settling. Preferred orientation of crystals

by plastic deformation due to shear was found in several places on glacier tongues.

(4) *Stratification bands.* Two types of bands are distinguishable in the *névé*, (a) dirt bands, which form on the surface and represent the boundary between the accumulation of successive years, and (b) ice bands, which are also of sedimentary origin; the crystal orientation of these is similar to that of pond ice. Other types of bands are to be seen in glacier tongues; of these the most important are the 'blue bands' which are of tectonic origin. Bands of sedimentary origin are also found in the glacier tongues.

(5) *Glacier flow.* Fundamental differences were observed between the mechanism of flow in the *névé* region and in the ice of the tongue. Measurements of the differential movement in firn together with the crystallographic evidence showed conclusively that flow takes place by the haphazard motion of crystals or small crystal aggregates. Below the firn line, where the interlocking of crystals prevents their relative motion, the glacier flows by plastic deformation and also by laminar movement along thrust planes. Plastic deformation involves the slip of crystals along their basal glide planes and is accompanied by the growth and reorientation of crystals due to a molecular transfer across their grain boundaries.

Full accounts of the work will be published in the near future.

Distribution of Radioactive Sodium after Injection into the Rabbit

RADIOACTIVE sodium has been administered to rabbits in the form of sodium chloride and the subsequent distribution of the Na^{24} investigated by measuring the activity of samples of ached blood and tissues with a Geiger counter. The radioactive sodium (Na^{24} ; 14.8 hours period) was obtained by irradiating magnesium or sodium hydroxide with neutrons from a radon-beryllium source of about 500 mc. The total activity so produced corresponded to 2000–4000 impulses per minute on the counter used for recording.

After intravenous injection of the radioactive salt, the Na^{24} in the blood was found to reach a constant level in about 15–20 minutes (see accompanying graph). A similar constant level was reached in about the same time after intraperitoneal injection. Equilibrium was obtained more slowly following injection of the salt into the colon. Assuming that the sodium is evenly distributed in a fluid medium¹, it is possible to estimate from the ultimate constant level of the Na^{24} in the blood the volume in which it is dissolved. Thus, for example, in one animal (weight 3000 gm.) 22.5 minutes after intraperitoneal injection of Na^{24} , 5 c.c. of blood contained an amount of radioactive sodium corresponding to 15 impulses per minute. The total radioactive sodium in the body at this time, allowing for the overflow into the urine, would have given 2500 impulses per minute. Hence the volume of fluid in which this Na^{24} was dissolved must have been about 830 c.c., that is, 36 per cent of the body weight in water. Similar results

were obtained in the other animals examined, the fluid in which the Na^{24} was dissolved being about 30–35 per cent of the body weight in water.

There is accumulating evidence that most of the sodium of the animal body is distributed outside the cells, so that the volume calculated above may be taken as representing the extracellular fluid content of the rabbit. These results compare favourably with those obtained by other workers by direct chemical analysis of the tissues¹. Samples of ashed tissues have given similar results; for example, liver contained 85 per cent of its weight of extracellular fluid, muscle 35–40 per cent, etc. In two animals the heart muscle was found to be exceptional, the radioactive sodium present in this tissue after injection being more than that representing 100 per cent of the weight of the muscle in terms of water. This corresponds to a three-fold concentration of the Na^{24} in the heart as compared with other tissues, and is probably to be interpreted as absorption of the radioactive sodium into the cardiac muscle cells.

The method of preparing Na^{24} used in these experiments is tedious and produces too little activity to allow of very accurate measurements, but with sufficiently active sodium produced by a suitably powerful apparatus, the injection of Na^{24} into the animal body may provide a useful method for the estimation and study of the extracellular fluid content of the tissues. Such a technique might be useful in other physiological experiments, or as a clinical guide to extracellular fluid in such conditions as oedema, Addison's disease and the post-operative administration of fluid.

A Difference of Effect Between the Oestrogenic Hormones and Diethylstilboestrol

In a previous investigation¹ it was shown that the oestrogenic hormones and progesterone are able to inhibit the comb-growth action of the male hormone. This action was described as antagonistic. The control determinations, carried out simultaneously, showed that in this case it was a question of a specific activity of the hormones, the mechanism of which is not yet

clear. The antagonism shows itself both on injection of the hormone and on smearing on the comb.

After the discovery of the oestrogenic activity of diethylstilboestrol by Dodds, Golberg, Lawson and Robinson² this substance was also investigated as to its antagonistic action (Mühlbock)³. By injecting this substance along with androsterone, it was demonstrated that the comb-growth activity could be suppressed in the same way as with oestradiol. No antagonistic action was observed, however, with diethylstilboestrol when it was smeared on the comb. Thus in this way it is possible to demonstrate biologically a difference between the oestrogenic hormones and diethylstilboestrol. It has not yet been explained why diethylstilboestrol fails to act when applied to the comb; possibly it is not resorbed.

This biological difference between the oestrogenic hormones and diethylstilboestrol, besides being of theoretical interest, may also be of practical importance in so far as this method makes it possible to establish what type of substance is responsible for the oestrogenic action. For practical purposes, only the following oestrogenic substances come into question: oestrone, oestrone benzoate, oestradiol and oestradiol benzoate. Hence these oestrogenic substances were examined as regards their antagonistic activity and compared with diethylstilboestrol.

Experimental method. When 0.4 γ of testosterone dissolved in 0.2 c.c. of oil is smeared twice daily (0.1 c.c. each time) for four days on the comb of a capon, on the average, a comb-growth of about 15 per cent is observed in five days. Six capons were always taken for each experiment and six other capons always served as controls. The combs were measured by the photo-electric process worked out in the Amsterdam Institute⁴. In the actual experiments the oestrogenic substances were smeared together with 0.4 γ of testosterone on the combs of the capons.

In order to bring about a complete suppression of comb-growth activity of the testosterone, 5,000 International Units of the oestrogenic hormones are sufficient.

Daily dose in 0.2 c.c. oil	Average percentage comb-growth in 6 capons after 5 days	Result
Experiment 1		
0.4 γ Testosterone	+ 13	Control
0.4 γ Testosterone + oestradiol 5,000 I.U. = 250 γ	0	Total suppression
0.4 γ Testosterone + oestradiol benzoate = 650 γ	+ 3	Total suppression
0.4 γ Testosterone + oestrone 5,000 I.U. = 500 γ	- 7	Total suppression
0.4 γ Testosterone + oestrone benzoate = 2,000 γ	- 4	Total suppression
0.4 γ Testosterone + diethylstilboestrol 5,000 I.U. = 250 γ	+ 12	No suppression
Experiment 2		
0.4 γ Testosterone	+ 21	Control
0.4 γ Testosterone + diethylstilboestrol 10,000 I.U. = 500 γ	+ 18	No suppression
0.4 γ Testosterone + diethylstilboestrol 20,000 I.U. = 1 mgm.	+ 21	No suppression

In the accompanying table, only one example of each oestrogenic substance is given. In the first experiment with testosterone, we obtained an average comb-growth of 13 per cent. The same comb-growth (12 per cent) was obtained when simultaneously with testosterone diethylstilboestrol was smeared. Contrary to this result, all the other oestrogenic substances suppressed the comb-growth

completely. Thus this method of working provides us with the possibility of distinguishing these two groups of substances biologically from one another. The cause of the different action of diethylstilbestrol is at present being investigated more closely.

Cycle of Responsivity of Castrated Albino Mice and of Human Beings to Oestrone Injection

In her recently reported observations on seasonal rhythm in the responsiveness of castrated mice to injections of oestrone, Dr. J. Duszyńska states that the response is more than three times as great in May as in November¹. She raises the question as to whether a similar rhythm exists in the human.

Such an observation, of course, is somewhat difficult to correlate with studies made on the human female whose gonads are still present and functioning cyclically. There does appear to be a seasonal rhythm, however, in the values for blood oestrogens found in normal males². Moreover, it is much more common to find high values for blood oestrogens³ in pregnant women in the late winter and spring than in the summer, in this part of Canada at least. This can be correlated with an increase in the late winter and a decrease in summer in the incidence of pathological states closely related to high values of blood oestrogen, such as certain pregnancy toxemias and abortion. We have postulated, on account of the reciprocal relation existing between ingested vitamin E and the blood oestrogen, that this is due to the seasonal tides in intake of this vitamin. In administering anti-oestrogens it is essential to take this variation into consideration⁴.

If Duszyńska means that only one third as much oestrogen has to be administered in May as is required in November in order to produce the same degree of response, her data parallels ours.

Effect of Zinc on the Iodine-Consuming Power of Insulin

THE duration of the blood sugar lowering action of insulin injected by the subcutaneous route is prolonged by the addition of zinc salts¹. The action of crystalline insulin containing zinc is of longer duration than that of an equal number of units of a preparation free from zinc.

This zinc effect is not found when rabbits are used, since apparently no difficulties are encountered in the assay of insulin of varying zinc content by the widely used rabbit method. Experiments with diabetics, however, have shown that this zinc effect is readily demonstrable^{2,3}, and rather severe clinical

disturbances were observed when a crystalline insulin was substituted for a zinc-free preparation (insulin containing less than 0.1 mgm. zinc per 1000 units is considered zinc free)⁴.

As the onset of the action of insulin appears to be retarded in the presence of zinc⁵, one is led to the assumption that the insulin cannot become fully active unless the zinc, which shields an active part of the molecule (by the strong hydration of the zinc ion⁶), is split off.

With the view of finding out whether zinc exerts a protecting action also *in vitro*, I examined the action of iodine on insulin. The iodine-consuming power of insulin was measured at pH 7.2 in the presence of calcium, aluminium, cadmium, zinc and lead.

It was found that the addition of zinc (and to a smaller degree probably also of cadmium) decreased the iodine consumption. Calcium, aluminium and lead showed no effect. The magnitude of this zinc effect is a function of the physiological activity of the insulin preparation used. These findings suggest the possibility of a purely chemical explanation of the physiological effect of zinc on the action of insulin. Moreover, a chemical method of assay of insulin appears to be made possible by the fact that my experiments showed the existence of a definite relation between the iodine-consuming power of insulin and its physiological action as measured in units.

Details of the experimental results will be published elsewhere.

Chlorophyll Formation and Development of Photosynthetic Activity in Juvenile Leaves of Mango (*Mangifera indica*)

THE question how far the development of photosynthetic activity is concomitant with chlorophyll formation has not been definitely answered; the investigation in higher plants being mainly along two lines: (1) relationship between rates of photosynthesis and chlorophyll formation in leaves in different stages of development; and (2) relationship between the two during the greening of etiolated seedlings.

(1) Willstätter and Stoll¹ observed that in the developing leaf both the chlorophyll content and photosynthetic rate increase but not in any definite proportion. Singh and Lal² noted that mature and old leaves, although containing a greater amount of chlorophyll than the younger, fail to show a proportionate increase in the photosynthetic rate. Briggs³ finds in seedlings developing a specialized photosynthetic organ different from the storage, the activity is not developed until some time after germination, while in those with the storage and the first assimilatory organ the same, there is no lag between the development of chlorophyll and that of full photosynthetic activity.

(2) Irving⁴ concludes that chlorophyll is not a limiting factor in the earlier stages of the developing

assimilatory organs; the beginning of photosynthetic activity being controlled by some other component part not developed by illumination as rapidly as the green pigment. Briggs¹ found that the assimilatory power of young shoots depends on their age rather than on chlorophyll content.

Emerson², using *Chlorella*, demonstrated that chlorophyll content was a limiting factor. However, as mentioned previously³, *Chlorella*, being a unicellular organism with the simplest mechanical arrangement for carbon dioxide diffusion, is not strictly comparable with multicellular leaves.

The results recorded by us with respect to chlorophyll formation, photosynthetic activity and absorption of radiant energy at different stages of juvenescence in the leaves of the perennial tropical plant, mango, appeared to throw interesting light on the question. Photosynthetic rate and chlorophyll content were determined by methods outlined before^{3,4} and absorption of radiant energy by a new method to be described elsewhere.

In the earliest stage, the primordial (leaf bud), the true assimilation rate (mgm. of CO₂ per 10 gm. fresh weight) is 0, the chlorophyll content (mgm. per 10 gm. fresh wt.) being 0.12. After three days, the assimilation rate rises to 0.9 and chlorophyll content to 1.10. The assimilation number of 0.82 at this stage increases to 6.17 at the tenth day, when assimilation rate is 18.5 and chlorophyll content 3.00. On the twenty-fifth day, the assimilation rate is 51.6, chlorophyll content 14.10 and assimilation number 3.65. Thus assimilation rate increases continuously but not in proportion to the chlorophyll content as evidenced after the tenth day by decreasing assimilation numbers. The leaves until the tenth day show increasing shades and after that decreasing shades of red coloration, being completely green only at the twenty-fifth day. On the thirtieth day, that is, the mature stage of the leaves, the assimilation rate falls to 48.4 although chlorophyll still shows an increase (16.50 mgm.). At the earliest stage, 0.5 per cent of the incident energy in the red region of the spectrum and 0.3 per cent in the blue only are absorbed; at the stage of active photosynthesis, that is, the tenth day, the absorption being 8.0 per cent and 4.1 per cent, and at the mature stage, that is, the thirtieth day, 27 per cent and 18.4 per cent in the red and blue regions respectively.

There is thus no proportionality between the development of photosynthetic activity and chlorophyll formation. According to Irving⁵, probably the youngest leaves (until the third day), although possessing chlorophyll, lag behind in some other part of the photosynthetic machinery. The latter, as suggested by Willstätter and Stoll⁶, may be then having a controlling influence resulting in increasing assimilation number, and after the tenth day when the red colour is disappearing this factor may be less active.

On considering the above results in conjunction with the findings of Briggs¹, the juvenile leaves of the perennial mango appear to conform to the type of those of the seedlings in Briggs's experiments, where the storage organ is different from the first assimilating organ; the photosynthetic activity in consequence lagging behind chlorophyll formation. The lack of immediate necessity for active photosynthesis by these young leaves is evidenced by the fact that at this stage the mature green leaves of the previous season are still present with active assimilatory power.

The evidence of a stage in the development of a leaf with no photosynthetic activity, a marked lag in the same as compared with chlorophyll formation and a corresponding lack of absorption of photosynthetically active components of radiant energy until the stage of active photosynthesis in a perennial plant like the mango, is interesting and appears to bring into unison the conclusions of the two main lines of investigation discussed above.

Behaviour of Mature Male Salmon Parr, *Salmo salar* juv. L.

IN a recent account of early and normal sexual maturity in male salmon parr in the Welsh Dee¹, we directed attention to the possibility of these young mature males behaving differently in their river movements from other young parr of the same age, immature males and females. The absence of mature males from one tributary, Hirnant Brook, at the time of examination indicated that they might have migrated; but as the sample was a very small one consisting of eleven individuals, the discriminating behaviour of the mature male could only be regarded as a possibility. In November, however, significant information was obtained. Pure samples of mature male parr were found on November 14, 16 and 18—coincident with the ascent of the last batch of adult spawners up the River Alwen—to have collected in numbers (twelve, sixteen and twenty respectively) in the stream-like race or overflow from a set of salmon-keeping tanks built into the bank of the River Alwen at Pont Barcar Weir. The race runs alongside the river and is separated from it only by a revetment wall, around the lower end of which the race runs into the river with a fall of a few inches.

No other parr than these forty-eight mature males, all of which were running ripe, were found in the race. But it may be mentioned that, when the earlier batches of salmon were 'running', salmon parr were occasionally found temporarily stranded in their efforts to negotiate one side of the weir at Pont Barcar. It would appear, therefore, that either the mature males are much more active than other parr, or that mature parr had approached the weir on an upstream migration and had entered the race in numbers as a promising easy upstream path.

An alternative or additional attraction of the race may lie in the fact that large mature females and males were being stored in the tanks from which the race water was derived. If mature male parr are attracted to the mature females chemotactically, they would tend to accumulate in the race while females were in the tanks.

A solution to the problems may be found experimentally in the future, but it is clear that the movements of mature male parr at spawning time can be different from those of other parr, and that upstream

or downstream migration and positive chemotaxy may possibly occur. Differential movement in mature male parr helps to account for their congregation on redds with spawning females. Many unpublished observations on the latter phenomena have been communicated to us since the publication of the paper noted above. Definite proof of the actual spawning of male parr with adult females is still nevertheless awaited, however probable it may seem. The probability is perhaps rendered greater by the fact, noted by Pearson² (after Worth), that in another anadromous fish, the striped bass, *Morone saxatilis* (Walb.), 20-50 young males each of not more than 2 lb. in weight may spawn with one large 5-20 lb. female in the rapid rivers which this species frequents for spawning.

Thermostatic Action of Textile Fibres

THE part played by heat evolved during absorption of water vapour by a porous body on rate of diffusion of water vapour into the body has been examined mathematically by P. S. H. Henry¹. In the laboratories of the Wool Industries Research Association similar problems have been studied, and experimental results obtained indicate that in addition to control of rate of conditioning (establishment of moisture equilibrium), absorption of water vapour by fibres and the attendant evolution of heat have an important significance in determining rate of propagation of temperature changes through fabrics. This effect is such that it cannot fail to have a bearing on the relative hygienic properties of textile fibres.

Our experiments have eliminated diffusion through air by evacuation, and under these conditions the time-regain (percentage moisture content relative to dry weight) curves obtained can be accounted for by change of temperature of the fibres alone; that is, the time required for equilibrium-regain to be attained when relative humidity is changed is small compared with the time required for appreciable heating or cooling of the fibres.

The time required in air at atmospheric pressure for change of regain is also small enough to be taken as zero compared with that required for any thermal change when allowance is made for diffusion effects. In normal atmospheres, water vapour pressure is roughly constant; for example, it is roughly the same indoors and outdoors on any given day. Consider a fabric taken from a hot to a cold region in this atmosphere. When the fabric temperature decreases, the relative humidity relative to the fabric increases, since the water vapour pressure is constant, and it begins to absorb water vapour. Heat of absorption is evolved and this tends to bring the fabric back to its original temperature. Resistance to temperature change from this source is very much more than can be obtained from ordinary diffusivity, because the specific heat factor is virtually replaced by a latent heat one, and the effective diffusivity becomes small.

This of course is only true if the fibres absorb water rapidly, which most textiles used for clothing are able to do in virtue of the small diameter of their

fibres. Differences between their thermostatic action will be determined by the quantity of water absorbed for a given change in relative humidity.

The relative importance of specific heat and regain may be readily appreciated from the example of a kilogram of wool fabric taken from an indoor temperature of 18° C. and 45 per cent relative humidity to an outdoor one of 5° C. and 95 per cent relative humidity. It must lose 4,000 calories because of the specific heat of the fibres, but it must lose 100,000 calories because of change in regain. A human body per cent before its temperature reaches the exceptional value. The latter is as much heat as a man can normally lose in one hour, and shows that the additional thermostatic action that textile fibres have in ordinary atmospheric conditions provides they absorb water vapour sufficiently rapidly.

The importance of water vapour to the thermostatic action of textiles has been demonstrated in these laboratories by comparison of the time required for propagation of temperature changes through fabrics in normal atmospheres and in dry air. Details of this work and its theoretical and practical implications will be published elsewhere.

Structure of Metals under Deformation

IN recent work on the deformation and fracture of metals under static and fatigue tests, it was shown that originally perfect grains were systematically dispersed into crystallites. The interesting feature of the process was the appearance of a lower limiting size, about 10⁻⁴ cm., below which the crystallites could not be broken down further by the modes of deformation employed¹.

Other work has now been carried out on metals of high purity under greater degrees of deformation than those occurring in the usual mechanical tests, and this work, whilst in general confirming the above principle, has brought out the following new points. In the first place, the lattice size, defining the interatomic distance within the crystallites, is not necessarily the same as that of the original perfect grains. In pure copper, the lattice expands. The effect may be measured easily by the X-ray diffraction spectrum of the metal, and is illustrated by the accompanying photographs obtained by a back-reflection method specially adapted for precision work. Fig. 1 is from the initial annealed material; this photograph corresponds to one given when the incident X-ray beam covers sufficient large grains to give continuous spectral lines, and is reproduced merely to show what the relative sharpness and positions should be of the characteristic (400) α_1 , α_2 doublet and (331) β lines under the experimental conditions employed. Fig. 2 is from the same specimen after 81 per cent reduction in thickness by cold rolling; this shows clearly that apart from the great diffusion of the lines (due to the onset of the crystallite formation), there is a bodily shift of the (400) line to the right; the effect may be seen conveniently by eye on noting the difference in separation of the (400) line from the (331) line, the latter being much less affected as it occurs at a smaller diffraction angle. The direction of the shift corresponds to an increase in lattice size.

A further point is illustrated by Fig. 3, obtained after continuing the reduction of the specimen to 90 per cent. It will be seen that the extra working has caused a reversion of the lines towards their original positions, and, at the same time, has produced some decrease in the breadth of the lines. This dual change corresponds to partial recovery in internal deformation and overall size recovery in internal deformation. Actually, these effects are to be noted at a much earlier stage, after some 20 per cent reduction; then, further working of the specimen to 90 per cent reduction; then, leads to the abnormal partially recovered state again recovers, the internal deformation, and this in turn structure varying between the two

RELATIVE SHIFT AND DIFFUSION OF (400) AND (331) X-RAY LINES OF COPPER ON DEFORMATION.

limits according to the balance at the moment of examination. This result indicates directly that the greater breakdown represented by Fig. 2 is in unstable equilibrium, whereas the partially recovered state is comparatively stable, and thus gives a meaning to the lower limiting size referred to in the earlier work.

These changes in structure may have a bearing on the mechanism, still to be elucidated, of the formation of the first cracks which precede and precipitate failure of a metal under strain, for it is reasonable to expect that the change in volume of the crystallites as they are formed along the slip bands will produce an internal stress tending to separate the neighbouring less deformed regions.

Differential Threshold for Viscosity

IN the course of some experiments on the capacity of the human senses to distinguish certain physical properties of colloidal materials, we have had occasion to determine the differential threshold for viscosity, using truly fluid bitumens* having viscosities of the order of 10^6 poises at 18°C .

Thirteen subjects were chosen having widely different experience and training. The samples of bitumen were presented in pairs to each of them with a request for a report as to which sample, if either, was the softer. The samples were squeezed by the subject under water kept at constant temperature. The thirteen subjects between them judged twenty-five pairs of bitumen samples thirty times in all. The samples differed from each other by 0, 7.5, 15, 22.5 and 30 per cent in viscosity. The viscosities were determined by the method of rheograms, slightly modified¹.

There was no significant difference in ability to distinguish viscosities between subjects differing in technological experience, scientific training and general education, although it is possible that age and sex may have had a very slight effect.

The results from the different subjects are combined in the accompanying table:

	Pairs differing in viscosity by:				
	0%	7.5%	15%	22.5%	30%
% correct	22	50	63	71	80
% given as equal.	22	28	20	15	12
% given in reverse order	—	27	17	14	8

This table shows that the percentage of correct judgments becomes significantly above 50 per cent for a viscosity change of about 10 per cent, and reaches an 80 per cent level at a difference of about 30 per cent.

Experiments on the threshold for shear modulus in elastic materials are in progress. Details will be published elsewhere.

Excitation of Nebular Lines

THE note which was added in proof by Menzel to his letter in NATURE regarding the effect of collisions on the intensities of nebular lines¹ prompts me to make the following remarks. In presenting the results to which he refers to the San Diego meeting of the Astronomical Society of the Pacific last June, I pointed out that a probable reason for the increase in intensity with pressure of the forbidden transitions in nitrogen is that the rate of production of the metastable states increases more rapidly with pressure than does the rate of de-excitation. It is quite probable that the process of excitation of the metastable nitrogen molecules and atoms in the afterglow is a much more complex process than the production of excited states in nebulae.

Regardless of this difference, however, it seems that Menzel's use of my experiments as observational proof of the points raised in his letter is a proper one. In fact, experiments at higher pressures and in smaller tubes have resulted in even higher relative intensities for the metastable transitions than those reported last spring. It is gratifying to see that my prediction of the possible astrophysical interest of these results has already been justified.

Conversion of Vitreous and Monoclinic (α) Selenium to the Hexagonal Modification

SELENIUM is known to exist in several stable allotropic modifications, of which the structures of the hexagonal and the monoclinic varieties (α and β) have been determined by Bradely¹ and Klug² respectively.

Prins and Dekeyser³ have investigated the gradual conversion of vitreous or amorphous selenium into the hexagonal variety at high temperatures and have also studied the influence of tension on this conversion. From their experiments they concluded that:

(a) The transformation of vitreous selenium into the hexagonal variety may take place at as low a temperature as 60° C., if a thread of vitreous selenium is kept under tension at that temperature.

(b) In the absence of tension, the crystallization does not take place below 73° C. The tension, therefore, helps the devitrification of vitreous selenium; and the fact that the degree of crystallization is most marked in the surface layers of a heated selenium stick and gradually becomes less in the deeper layers has also been suggested by them as due to the presence of mechanical stress, already present in the surface layers owing to the 'quenching' method of its preparation.

In the course of our investigations on selenium, we have obtained results which in many respects deviate from those of the previous authors. We find that, if thoroughly powdered specimens of vitreous selenium be maintained at a temperature even as low as 43° C., devitrification of the specimen sets in and gradually progresses with the period of heating, and after a considerable period, say about two weeks, a complete transformation into the hexagonal variety is clearly indicated by the appearance of only sharp diffraction rings on a clear background in its X-ray powder diagram. The powder-pattern obtained in this final stage is reproduced in the accompanying figure (taken with a hemicylindrical camera).

In the experiment mentioned above, we used powdered sticks of vitreous selenium; the diffracting specimen evidently consisted mostly of particles lying in the deeper layers or in the body of the sticks,

where the material is supposed to be free from any mechanical stress. Thus the experiment shows that even in the absence of tension, crystallization of vitreous selenium is possible at 43° C., if not at still lower temperatures. Insufficient period of heating the specimen is undoubtedly the cause of failure of the previous authors³ to detect the crystallization, which is extremely slow at lower temperatures.

In the case of monoclinic (α) selenium, we also find that the transformation into the hexagonal variety is quite rapid at 100° C. and may be detected after 24 hours of heating, whereas the same process is so slowed down at 80° C. that it cannot be detected before several days have passed.

Experiments are in progress to determine the lowest temperature at which these transformations take place. We are of opinion that in every case of monotropic structural transformation there is a critical temperature, below which the transformation in question cannot take place. At this temperature the molecules of the substance acquire the mobility which is required for their correct marshalling in the new structure.

A rise of temperature in all these cases increases the time-rate of conversion and thus minimizes the time required for the complete conversion of the whole specimen. Another example of this type of monotropic change which has been thoroughly studied by one of us⁴ is the conversion of Se or white sulphur into S₂ or orthorhombic sulphur. Here both Se and S₂ are the two different crystalline phases of sulphur.

Results of the investigation on selenium will be published in more detail in the *Indian Journal of Physics*.

Spectrum of Potassium Deuteride

A PRACTICALLY uncontaminated KD spectrum was obtained in an arc between potassium (negative) and nickel (positive) electrodes burning in a deuterium atmosphere of 50–30 cm. mercury pressure, and was photographed in the first order of a 15-ft. grating spectrograph having a dispersion of 3.7 Å. per mm.

In the strongest part of the many-lined spectrum between 4300 Å. and 5100 Å., the $v' = 0$ progression bands $7 \rightarrow 0$, $8 \rightarrow 0$. . . $20 \rightarrow 0$ of the KD $^1\Sigma \rightarrow ^1\Sigma$ system were found and analysed. At this dispersion, overlapped lines are still numerous and reach up to half the number of lines (60–80) in each band.

The rotational functions of both upper and lower states are anomalous in having a maximum in $\Delta_2 T_r/4J + 2$ at about $J = 20$, and $T_r(v, J)$ must be expressed by terms with positive D_2 , negative F_2 , etc. However, this point should be examined with a larger dispersion, and preliminary values of rotational constants were calculated according to the usual three-term formula adjusted to the $J > 20$ regions. B'_2 can be given by $B'_2 = 0.673 + 0.00391(v' + 1/2) - 0.000281(v' + 1/2)^2$ within ± 0.005 , $D'_2 = -1.4 \times 10^{-4}$, and $B''_2 = 1.641$, $D''_2 = -1.8 \times 10^{-4}$.

As the result of vibrational analysis, null-lines of the observed fourteen bands, evaluated from small

	KD upper state	KH upper state	ρ^a
ν_4'	180.26	254.5 (Almy and House) ¹ 240.18 (Hori)	0.5017 0.5053
ν_4''	0.573,	1.844 (Almy and House) 1.311 (Hori)	0.5013 0.5139
		Theoretical	0.5129

J lines to minimize the possible errors in computing rotational energies, can be expressed by

$$\nu_0'' = 19,229 + 180.26(\nu' + 1/2) + 2.204_4(\nu' + 1/2)^2 - 0.05281(\nu' + 1/2)^3,$$

within $\pm 2 \text{ cm}^{-1}$. Here again the vibrational function $G''(\nu)$ is characterized by positive x_2 . From the above given constants the isotope coefficient ρ comes out as indicated in the table.

Further analysis of the system is under way and will be published in the *Scientific Papers* of this Institute.

Points from Foregoing Letters

THE movable 'thumb' of the giant panda, which it uses for the purpose of grasping bamboo shoots, is not a true first digit, writes Prof. F. Wood Jones. The actual thumb of the panda, as of all animals which use all four limbs for supporting the body on the ground, has lost its movability and the animal has developed a new movable digit, rather than reverse its structural evolution (Dollo's law).

A modified method for determining the electronic charge on an oil droplet is described by Prof. T. H. Laby and V. D. Hopper. A horizontal electric field is employed and the movement of the droplet is recorded photographically, so that a displacement of $3 \times 10^{-5} \text{ cm.}$ can be measured. Experiments of a preliminary nature indicate for the electronic charge a value slightly lower than that found by Millikan.

Sir James Jeans criticizes the assumptions of Gamow and Teller in their discussion of the genesis of the great nebula. He concludes that the universe as it now stands could be formed by the condensation of a gas with a 'thermal' velocity of about 20 km./sec., that is, from a mixture of atoms and electrons at any temperature between -260° and $19,000^\circ \text{ C.}$

The volume of extra-cellular fluid in various organs has been calculated by Dr. J. H. E. Griffiths and Dr. B. M. Macgraith from determinations of the radioactivity of blood and tissues of a rabbit after injection of radioactive sodium chloride—assuming that the sodium is mainly distributed outside the cells. They find, however, that a certain amount of radioactive sodium is absorbed by the cardiac muscles.

Dr. O. Mühlbock finds that diethylstilboestrol, unlike the oestrogenic hormones, does not suppress the comb-growth action of the male hormone, progesterone.

Commenting on Dr. Duszyńska's observation that the response to oestrone in albino mice is three times as great in May as in November, E. V. Shute states that there appears to be a seasonal rhythm in the proportion of oestrogens found in normal males; also the blood oestrogens in pregnant women are greater in late winter and spring than in summer; this can be inversely correlated with the intake of vitamin E.

Dr. E. H. Vogelensang finds that the addition of zinc decreases the iodine consumption of insulin. The magnitude of the zinc effect is a function of the physiological action of the insulin preparation, and the author believes that it may eventually serve as a basis for the chemical estimation of insulin activity.

Prof. B. N. Singh and J. D. Jha find that in the young leaves of the mango the assimilation rate of carbon dioxide increases continuously but not in proportion to the chlorophyll content. The behaviour is similar to that observed by Briggs in the case of seedlings where the storage organ is different from the first assimilating organ and the photosynthetic activity lags behind chlorophyll formation.

Observations on the movement of mature male parr in the Welsh Dee are reported by G. M. King, J. W. Jones and Prof. J. H. Orton, suggesting that at spawning time such movements can be different from those of other parr, and that upstream and downstream migration and positive chemotaxy may occur.

Rate of absorption of water vapour by wool fibres is rapid when the external restrictions of diffusion and thermal change due to heat of absorption are removed. It is suggested by Dr. A. B. D. Cassie, Dr. B. E. Atkins and G. King that this fact is of importance for the hygienic properties of textile fibres and the propagation of temperature changes through fabrics in ordinary indoor-outdoor atmospheres.

Photographs of the X-ray diffraction spectrum of annealed and of subsequently cold-rolled copper at different stages are submitted by W. A. Wood, showing a relative shift and diffusion of the (400) and (331) lines. These indicate a breakdown into small crystallites, followed by a partial recovery in internal deformation and overall size of crystallites.

By comparing the judgments of thirteen subjects concerning the relative softness of samples of bitumen with the actual viscosity of the samples, Dr. G. W. Scott Blair and Miss F. M. V. Coppen find an 80 per cent correct judgment for viscosity differences of 30 per cent.

Research Items

Ancient Eskimo Houses of East Greenland

OWING to the inaccessibility and dangers of the East Greenland coast it has been infrequently visited by Europeans. The Anglo-Danish East Greenland Expedition of 1935, conducted by Mr. Augustine Courtauld, afforded an opportunity for supplementing previous inadequate archaeological information. An account of the excavations of house sites and graves and of the objects found at Skærgaardshalve, Ivnamut, I. C. Jacobsens Fjord and Cape Irninger in Knud Rasmussen Land has been prepared by Dr. Helge Larsen (*Medd. om Grønland*, København, 119, 8; 1938). At Skærgaardshalve, a well-known archaeological site, seven ruins were examined. These differed much from one another in shape and in state of preservation. In their interiors they were rectangular in plan, with somewhat rounded corners, and a house passage. They were built entirely of stones, more than one metre thick, which on the inside formed even perpendicular walls up to at times as much as nine courses of flat stones. On the outside the stones lie about loosely, giving the impression of a random heap of stone. The internal dimensions of the house first examined were 2.0 m. long by 2.10 m. broad. Of a different type, in which the greatest length of the structure is at right angles to the passage, was the 'common-house' form, in which two rooms adjoined with a dividing wall. The length of the first example found of this type was 7.5 m. At I. C. Jacobsens Fjord one house proved to consist of three houses, built one within the other. A common-house was evidently the oldest, as well as the largest, containing the others. It is concluded that the size of the habitation was reduced from time to time to meet the needs and convenience, for example, in heating, of a decreasing population. Analysis of the types of houses excavated and of the contained objects leads to the conclusion that they belong to the Inugsuk culture of West Greenland with elements from a later cultural stage in Angmagssalik. Its entry into East Greenland dates probably from the fifteenth or sixteenth century and it probably became extinct in the nineteenth century.

Avitaminoses and Endocrine Glands

B. SURR (*Endocrinology*, 23, 575; 1938) has investigated the influence of various avitaminoses on the weights of endocrine glands in animals (pigeons and rats). He found that in vitamin A deficiency there was a hypertrophy of the pancreas amounting to 40 per cent. In vitamin B deficiency there was a marked hypertrophy of the thyroids and adrenals. The most noteworthy change in endocrine weights was the marked atrophy of the thymus in vitamin B deficiency which occurred in 100 per cent of the animals. Hypertrophy of the pituitary was found in vitamin B₁ and vitamin B₂ deficiency to the extent of 40 and 25 per cent respectively. Repeated vitamin B₂ depletions of endocrine weights had the following effect: the hypertrophy of the pituitary entirely disappeared; in the thyroid it was reduced to insignificant proportions (9.1 per cent) and in the adrenals from 50 to 20 per cent.

Hypersensitiveness in Experimental Tuberculosis

R. H. FOLLIS, JUN. (*Bull. Johns Hopkins Hosp.*, 23, 283; 1938) has studied the effect of preventing the development of hypersensitiveness in experimental tuberculosis in guinea pigs as follows. He found that the lesions in guinea pigs infected with tubercle bacilli and prevented from becoming hypersensitive by subcutaneous injection of old tuberculum showed less caseation than those of control animals which developed hypersensitiveness. In some of the non-hypersensitive animals, pulmonary lesions developed which were marked by an extraordinary proliferation of acid-fast bacilli. Since these lesions did not develop in most of the non-hypersensitive animals and the same lesions were found in some animals of the control groups shown to be hypersensitive, Follis concludes that lack of hypersensitivity does not play a part in producing lesions of this type.

Improvement of Forage Plants

THE possibility of improvement of crop plants by hybridization has received a new impulse from the intensive work carried out within recent years in the U.S.S.R., where, among others, various *Triticum-Agropyron* crosses have been carried far enough to indicate possibilities of obtaining constant, perennial forms with advantageous qualities not possessed by annual wheats. L. P. V. Johnson now publishes the results of further crossing experiments between these genera which have been carried out with the view of obtaining improved forage plants, suited to the drier areas of western Canada (*Can. J. Res.*, 16; 1938). An extensive selection of *Triticum* types has been used as the ovule parents, with *Agropyron elongatum* or *glaucom* as pollen parents; the F_1 hybrids show a predominance of *Agropyron* characters. So far, all crosses with *A. glaucom* have proved sterile, but some fertile types occur amongst the *A. elongatum* hybrids. Russian investigators have already isolated types which are constant, fertile, drought and cold resistant, and productive—all qualities of value in forage plants; also types with high protein content of the grain, which suggests that possibly a plant might be obtained with good forage qualities combined with grain suitable for feeding purposes. In the present experiments some hybrids combine the extensive root system of *Agropyron* with the finer root texture of *Triticum*, a promising feature for growth in an arid zone, and the structure of leaves in some hybrids also suggests lines along which useful results may be obtained. The experiments need to be carried further before definite results can be stated, but the progress report augurs well for the final results.

Direct Oxidation of Soil Humus

MR. O. B. GREENING has published a preliminary account of the use of potassium permanganate for the oxidation of soil humus (*J. Roy. Hort. Soc.*, September 1936). He has now followed it by a more extensive paper (*J. Roy. Hort. Soc.*, 63, Pt. 12, December 1938). Garden refuse can be oxidized to organic manure by treatment of a heap with permanganate solution (1 oz. per gall. of water). More dilute solutions were applied to lawns, where they stimulated the growth

of grass, eradicated moss, destroyed 'mat' and controlled earthworms. Tomatoes and zonal pelargoniums grew better than normal when treated with still weaker solutions. The action of oxidizing agents might vary with soil type, or with acidity, and such possibilities have still to be appraised. Effects of the treatment have as yet, moreover, been estimated by the unaided eye; but a promising field of practical application is undoubtedly commended for further detailed investigation.

Properties of Broad-Bean Mosaic Virus

A MOSAIC disease upon broad beans was recorded from Japan in 1928, and has since appeared frequently. Characters of the causal virus have been studied by Daiki Murayama (*J. Fac. Agric. Hokkaido Imp. Univ.*, 44, Pt. 1, pp. 32 and 1 pl., Oct. 1938) who considers it to be similar to the pea virus 2 of Osborn, or pea virus 3, Pierce. The virus extract appears to be of medium virulence, and will not pass even coarse ultra-filters. It is inactivated by heating for 10 min. at 63° C., by ageing for 25 days and by 50 per cent alcohol or 1 per cent formaldehyde acting for 30 min. Extracts were also inactivated when acidified to pH 3.0, or when their alkalinity was increased to pH 9.5. A precipitation which deprived the extract of its power to infect, occurred under the latter conditions. Symptoms of the disease are given, and a useful table of comparison of the physico-chemical properties of numerous mosaic diseases of leguminous plants also appears in the paper.

New Dermatophyte Fungi

Mosses. K. B. Boedyn and J. A. Verbunt have undertaken the examination of dermatophyte fungi on cases in the Medical School at Batavia since 1935. Their investigations (*Mycopathologia*, 1, Fasc. 3, Sept. 1938) have led to the recognition of three new species of fungi which attack human skin. *Proteomyces variabilis* causes red spots in the trigonum scarpæ of the male. *Favotrichophyton decipiens* attacks hair, causing a white sheath composed of spores of the fungus. *Piedraia javanica* is an interesting ascomycete which forms hard, black nodules upon affected hairs. *Piedraia* is a genus formed by the removal of the conidial form *Trichosporum* from the Fungi Imperfecti, upon the discovery of the ascigerous stage.

The Earth's Crust near New Zealand

K. E. BULLEN has recently made considerable progress in the study of the crustal layers near New Zealand by considering afresh in the light of all the available evidence the Wairoa earthquake of September 15, 1932 (Dominion Observatory, Wellington, W.1, New Zealand, *Bull.*, No. 136; 1938). Taking the S_1 reading at Arapuni to be really S^* , an analysis of the P and S readings from all stations indicates an epicentre for the shock at 38.9° S., 177.55° E. and an origin time 13 h. 55 m. 0 s. G.M.T. These are confirmed by P' readings in the opposite hemisphere and macroseismic evidence, and the epicentre is accurate to within 0.2°. The new evidence, along with other considerations, leads the author to a structure from the earth's surface downwards as: sedimentary layer several kilometres thick with P and S velocities 5.0 and 3.0 km./sec. respectively; granitic layer very thin; intermediate layer probably double with a P_y velocity in the upper part of 6.0 km./sec., and the lower part 15 ± 5 km. thick with normal P^* and S^* velocities. This P_y velocity

is similar to that observed in California. These results are stated to be tentative, and the results of further work on near earthquakes in New Zealand are awaited with interest.

Design of Small Induction Motors

IN a paper read by Mr. N. F. T. Saunders on January 19 to the Institution of Electrical Engineers, the design of small motors was discussed, and it was pointed out that methods of designing large induction motors are not applicable to machines of less than about one horse-power, called fractional horse-power motors. The author, using analytical methods, establishes simple formulae for the performance data required in connexion with single-phase induction motors. He then uses correction factors which make the results accurate. He also discusses polyphase induction motors and shows that similar correction factors can be used in their case. These correction factors are based on the conditions usually existing in small motors, which differ appreciably from those found in large motors. For small motors the main factors to be considered are a powerful starting torque and high overload capacity. The modern tendency is to demand silent running, and so the steps necessary to eliminate noise of electrical origin are important factors in the design. As the majority of small machines have to operate at 1,500 r.p.m., that is, they have four poles and run at 50 cycles per second, it is customary to develop standard designs having ratings of an eighth, a sixth, a quarter, a half and three-quarters horse-power with the maximum economy in material. For other speeds the same frames with modified stampings can be used. Several different starting methods for single-phase motors are in use. The most popular at the present time is the capacitor (condenser)-start, the success of which is due to the advance in the technique of electrolytic condensers. An important conclusion arrived at is that the difference between the e.m.f.s at full and no loads will generally produce a marked difference in the iron loss. Hence if the full load efficiency is computed by the 'summation of losses' method the result obtained for the efficiency is too low. For this reason it is recommended that fractional horse-power motors should be tested by a brake method.

Inclination of the Spiral Nebulae to the Line of Sight

F. G. BROWN showed a year ago that the inclinations to the line of sight of the planes of the extragalactic nebulae which were more than 2' in diameter were small, and that the preponderance of small inclinations was due to a systematic orientation of the planes in space. Knox-Shaw examined the objects in the Shapley-Ames catalogue and came to the conclusion that the excess of small inclinations is non-existent. Brown (*Mon. Not. Roy. Astro. Soc.*, 99, 1; Nov. 1938) now shows that Knox-Shaw excluded an undue proportion of spindles more than 2' in diameter, owing to the integrated magnitudes of many of them being less than 13.0. For spiral nebulae not less than 4' in diameter, the Shapley-Ames catalogue confirms the apparent excess of small inclinations which Brown found by examining the Reinmuth catalogue. In addition, the Reinmuth catalogue shows the persistence of the excess down to 2' in diameter, and its existence is confirmed by the small nebulae down to at least 30" found in Fath's list. It seems certain that Brown has proved his point, and that there is a decided preponderance of small inclinations of the nebulae under discussion.

Geographical Aspects of Current Problems

ON January 3, Sir Thomas Holland delivered his presidential address to the Geographical Association, on the occasion of its annual conference at the London School of Economics. Taking as his title "The Geography of Minerals", Sir Thomas gave a penetrating analysis of economic and political effects of the unequal distribution of mineral wealth.

Until the Industrial Revolution, little interest had been taken in mineral wealth other than the precious metals, and world development was on an agricultural basis. Political boundaries took no notice of mineral fields. The Industrial Revolution placed a new emphasis on coal and iron, and later the development of steel-making and the more recent discoveries of the uses of alloy steels, together with the expansion of the electrical trades with their great demand for non-ferrous metals such as copper and lead, re-oriented the political outlook on minerals. More minerals were actually produced between 1900 and 1925 than during the whole previous history of the world, and although production is still lower in value than that of the field and forest products, it is increasing rapidly, and its effect on political geography is becoming more and more evident.

• The possession of, or free access to, a wide variety of minerals is now an essential to the well-being of a great nation, and the unequal distribution of resources, together with the post-War tendency to frustrate the normal or natural movement of raw materials, is at the bottom of much of the present unrest in the world. Both Germany and the Italian Empire are lacking in many of the essential minerals.

It is a striking fact of mineral geography that some seven tenths of the world's iron and steel industry is situated in the countries that border the North Atlantic Ocean. In no other area of the world do coal and iron come together in sufficient quantities ever to give rise to other great steel-producing regions like those of the eastern United States and western Europe. It is this industry which has so largely affected the accessory mineral industries (manganese, chromium, nickel, cobalt, tungsten, etc.). Between them, the United States and the British Empire own about two thirds, and control about three quarters, of the world's mineral industries.

The need for such a wide variety of minerals has meant that the former self-sufficiency of nations in respect of mineral requirements has gone for ever. More than ever before the nations are now inter-dependent. Here again it is noteworthy, however, that a wide variety of resources occurs in the areas which lie around the North and South Atlantic Oceans. Thus with the British Empire and the United States on friendly terms, and the Atlantic shipping routes under their control, neither Britain nor the United States need have any fears about the supply of any mineral at present considered as vital to industry, whether peaceful or warlike. This rather one-sided position only seems to emphasize the necessity for the interchange of mineral products between the nations, if civilization is not to be destroyed in the revolt of the 'have-nots' against the 'haves'.

In a symposium on India, at the same Conference, Sir Thomas Holland contributed a short survey of

India's mineral resources, dealing especially with coal and iron, manganese and chromite. Another contribution was from Lord Meston, who described in vivid terms the superimposition of British autocracy, which has converted a congeries of almost medieval peoples into a modern democratic State of 350 million souls, and the difficulties which rapid progress has brought. Dr. L. Dudley Stamp, in suggesting a division of India into physiographic regions, emphasized that the study of modern geography is still in its infancy in India, and that although the universities are now taking a lead, a vast field of work awaits the geomorphologist in utilizing and correlating the mass of material available in the publications of the Geological Survey and elsewhere. In the meantime, it is important that the main physical features of each of the major regions of India should be understood and regarded as an essential background to human and economic geography. Prof. H. J. Fleure finally gave a brief introduction to the study of the nature and origin of some of the Indian peoples.

Another topical item in the Conference was a lecture by Dr. Hilda Ormsby on the 'Sudeten' lands. Dr. Ormsby also spoke on the problem of Czechoslovakia to the annual meeting of the Institute of British Geographers, which was in session during the same week. Dr. Ormsby presented a clear picture of the geographical background of the recent crisis. Before the Great War, Bohemia was an outpost of Slavdom, forming the industrial core of the Austrian Empire, and fringed with a population of Germans who had filtered across the mountains from the west during many centuries. The Treaty of Versailles allied the Czechs to the Slovaks and Ruthenians, and cut off the 'Sudeten' Germans of the northern and western fringes of the new State from their Austrian motherland. This Bohemian 'salient' of Slavdom became a violent aggravation to the new Reich after the *Anschluss*, thrusting a spear-head into the heart of Greater Germany. The curious nature of many parts of the 'Sudeten' frontier, which, instead of following sparsely populated, forested country, frequently cut across populous areas, was a natural incitement to the reunion of the German-speaking peoples on either side.

The 'post-Munich' frontier, however, cannot undermine the essential geographical unity of Bohemia. The similarity of the industrial occupations on both sides of the highland frontier of Bohemia (the Ore Mountains, Giant Mountains and Sudetes) means that the 'Sudeten' lands are economically tributary to the interior of Bohemia rather than to Saxony, and the fact that the Czechs, for some years, had been removing industry from the 'Sudeten' regions into the heart of Bohemia, has rendered these areas poorer and more liable to unemployment. The new Czechoslovakia, although far more homogeneously Slav than ever before, can scarcely be regarded as anything but a puppet State, held together by the power of Germany. The new German motor-road along the Moravian corridor will sever completely the western and eastern parts of the country, and the main lines of rail communication between east and west have already been cut by the new frontiers in several places.

S. H. BRAVER.

Research in Fuel Technology*

THE growth in size of the annual report of the Fuel Research Board is an indication of the expanding work of this section of the Department of Scientific and Industrial Research, which was established in 1917.

This year special attention is directed to the progress made in the physical and chemical survey of the national coal resources, which was the first task undertaken by the Board. Looking back twenty years, it may surprise some to recall how meagre was the reliable information publicly available about the properties of British coal, considering the magnitude of the industry. Collieries usually had no use for a chemist, and such analytical figures as they possessed were commonly made on a few selected and unrepresentative samples. The larger industrial users often accumulated considerable information about their own fuels, but for their own use only. Conditions might be likened to an unmapped forest traversed by routes known only to local guides. The organization of the survey, which has no counterpart in any other coal-producing country, was not completed until 1932, when all the coalfields were brought under examination. Now complete surveys have been made on sixty-five seams, representing 30,000 million tons of coal, giving detailed and reliable data on one fourth of the proved British coal reserves.

The value of this information grows as the scheme progresses, particularly as regards processes of coal treatment prior to combustion. The more refinement is given to the utilization of coal, the more important it is to know exactly the idiosyncrasies of the raw material. Coals vary in a bewildering degree in properties which vitally affect their uses. Many processes of low-temperature carbonization have broken down on account of swelling or caking power. Again, the quantity and kind of ash or sulphur influences many applications. The behaviour of coal ash is still inadequately treated. There is no standard method of assessing and recording the density of coal ash although this affects the value of coal for many uses—especially as domestic fuels.

* Report of the Fuel Research Board for the Year Ending March 31, 1936. Pp. x+255. (London: H.M. Stationery Office.) 4s. net.

Further work is reported on the problem of dust-proofing coal, which has acquired prominence first in the United States. Coal is dusty to handle, and this dust production is both a domestic and an industrial nuisance. Marked effects in suppressing dust result from spraying oil upon the coal in quantities of the order of 1 gallon per ton. Investigation shows that some 'younger' coals need much more oil than those of older formation. Oil does not produce marked effects on the behaviour on combustion.

It has long been recognized that coal dust can serve as a fuel for internal combustion engines instead of fluid fuels. One of the main obstacles is the problem of getting the solid fuel into, and the ash residue out of, the engine cylinder after combustion, owing to the abrasive action of the latter on the engine parts. In spite of the difficulty, a solution of the problem would have immense value to a coal-rich country like Great Britain, and the task should not be lightly abandoned. Experiments are reported on the wear on cylinder parts produced in a petrol engine when coal ash is fed into the carburettor. The results suggest that by choice of materials it may be possible to reduce the wear to reasonable proportions. A Diesel engine has been installed at the Station and converted for use with coal dust fuel.

Work on the hydrogenation of coal and coal oils is being continued. It is often too easily assumed that tars and oils obtained by carbonizing coal at low and high temperatures are immediately valuable as substitutes for imported mineral oil. This is far from the truth, especially as regards the production of lubricants where molecular structure plays an important part in determining behaviour. By synthesis of hydrocarbons from water gas and polymerization, it is believed that products with satisfactory lubricating properties will be obtained.

These are only a few of the many subjects touched in this report, the 255 pages of which range over the whole field of fuel technology.

H. J. HODSMAN.

Earthing of Electrical Installations to Water-Mains

IT is well known that direct current causes electrolytic corrosion when it leaves a metal conductor or pipe to enter the earth, but there is still a difference of opinion as to whether alternating current has a similar deleterious effect. The very rapid expansion of the use of electricity in Great Britain, for motive power, for domestic applications, for use with radio sets and for agricultural applications has made it advisable that the whole question of earthing be discussed. It is known that electrolytic corrosion proceeds as a rule very slowly, and until large leakage currents have been flowing for many years, in several cases no apparent damage can be detected. A further point that needs discussion is the cause of

the electric shocks which are sometimes experienced by workmen when repairing water-mains. It was obvious that some agreement as to the conditions under which earthing-connections should be allowed was highly desirable.

The whole question was considered by a joint committee of the Institution of Electrical Engineers and the Metropolitan Water Board, as a result of which a draft memorandum on "Earthing to Water-Mains" was issued in December 1926. It was impossible, however, to conclude the negotiations by that committee alone. The rapid expansion of the applications of electricity to factories of all kinds in all parts of Great Britain made the question an urgent one.

In these circumstances, a sub-committee of the Institution of Civil Engineers Research Committee was formed in March 1936, to investigate the existence and extent of damage due to leakage currents, to carry out research work, if necessary, and particularly to obtain mutual agreement on the conditions under which earthing connexions to metal water-pipes might be made and to try, if possible, to formulate a set of regulations. The sub-committee included nominees from the various engineering associations chiefly concerned, and Mr. H. W. Swann, senior electrical inspector of factories of the Home Office.

The sub-committee has been successful in obtaining unanimous agreement on the conditions under which earthing connexions may be made, and has now issued its report*.

The first clause in the report is that an earth-wire connecting an electrical installation to a water-main or water-pipe is to be used only as a safety measure, for the purpose of returning to the source of supply such leakage current as may flow from the electrical installation, for radio currents, or currents from radio-interference suppression devices. In the second clause, it is forbidden to cut or drill or break a water-main or water-pipe. The third clause states that every device used must be of 'approved' design. The fourth clause states that due notice must be given to the water authority concerned when an earth-connection is made to a buried water-pipe. The fifth clause states that wherever an earth-connection is made to a water-main or water-pipe on any premises

* Regulations for Earthing Electrical Installations to Metal Water-Pipes and Water-Mains. Pp. 6. (London: Institution of Civil Engineers, 1938.) 6d.

in which a water-meter is installed, a suitable bond must be placed across it by the user, free of expense to the water authority. Finally, if the water supply authority has reason to believe that damage to water-mains or water-pipes is being caused by an excessive flow of electric current through the earth-connection, it can ask the electricity supply authorities for the district to test the installation in the presence of a representative of the water company. The water company can, if it requires, make its own test after advising the electric supply company.

Post Office installations, other than those for power and lighting services, are specially excluded from the application of these regulations, but are subject to agreement between the authorities concerned.

In the course of its work, the sub-committee came to the conclusion that there are certain other aspects of the problem which could with advantage form the basis of research. Funds have been subscribed for this research by the interests concerned, and the investigation has been undertaken by the British Electrical and Allied Industries Research Association. The programme of research so far approved is as follows: (1) The amount and effect of aggregate leakage currents on water-pipes. (2) The possibility of partial rectification of alternating currents in underground water supply systems, (a) at earthing connexions and (b) between metal pipes and the soil. (3) The possibility of primary cell effects in water supply systems. (4) The relation of all the above to the question of corrosion. The sub-committee is to be congratulated on its very practical report.

Social Science at Liverpool

THE publications of the Statistics Division of the Social Science Department of the University of Liverpool provide an admirable illustration of the valuable work which the universities can undertake in the field of social science. The latest addition to the New Merseyside Series ("Handbook of Social Statistics Relating to Merseyside": University Press of Liverpool. 1s. net) is no exception and indeed in some matters indicates a further function or responsibility of the university which undertakes such local studies—that of educating local opinion to secure requisite action on the facts disclosed.

This responsibility is very clearly implied in the opening section of this handbook, in which Mr. D. Caradog Jones directs attention to the marked tendency for the population of all four Merseyside boroughs to decline. The rate of natural increase in Liverpool is already less than one half the increase in the early years of the present century, and the rate of increase in Birkenhead is only one quarter of what it then was. He asks the pertinent question whether the serious effect of the anticipated decline upon the demand for houses, for schools, for transport, and upon the need for social services, has been fully appreciated by the local authorities, and, if or whether they are taking steps to deal with a situation that is likely to change rapidly.

In the face of these facts, local authorities will bear a heavy responsibility if on the contrary they

continue to legislate on the assumption that the talk about fall in numbers does not concern them, or that if it does there will be plenty of time to set their house in order when the fall begins to take place. None the less, having disclosed the true situation, scientific workers have some measure of responsibility for seeing that the facts are brought to the notice of those concerned with action in a sufficient, definite and convincing manner.

It would not be easy to improve on the lucid but brief presentation which Mr. Caradog Jones uses in this handbook. The section on trade gives an analysis of the trade of the Port of Liverpool in comparison with that of London and the next three most important ports of the United Kingdom. Liverpool showed a greater relative improvement than London in 1936 as compared with 1932 in the value of goods imported, but for exports the position is reversed. Cotton, imported raw and exported as manufactured textiles, holds an outstanding place in the trade of Liverpool and the figures indicated an appreciable increase between 1932 and 1936 in the home demand for manufactured cotton textiles as well as of woollen manufactures.

Statistics of employment alone at first suggest that the position on Merseyside is not discouraging. Actually Merseyside found employment in 1937 for 13,000 more insured workers than in 1929, which is generally regarded as the best all-round post-War

year. This figure, however, represents an increase of only 4 per cent as compared with a 12 per cent increase in Great Britain as a whole, and a 38 per cent increase in unemployment on Merseyside as compared with 18 per cent in Great Britain. Moreover, although the high level of unemployment on Merseyside has not altered very much in the last twelve months, the August figures indicating an increase of less than 2 per cent, the cost of its relief has increased. Unemployment insurance payments in August 1938 were nearly a fifth greater than in August 1937, while unemployment allowances were more than 5 per cent less. Although this position is due partly to the increases in benefit made this year by the Beveridge Committee and the fall in the cost of the means test, to long-standing cases getting work, to final 'cuts' under the 'Standstill Act', and to the revised system of relieving casual labour, the fact that the means test is costing less and benefit more, while unemployment remains much the same, is unexpected.

The cost of outdoor relief decreased between June 1937 and June 1938, but able-bodied unemployed still cost the ratepayers of Merseyside £38,000 a

month, £6,200 of which goes to insured workers. Mr. Caradog Jones refers once more to an unfortunate gap in the social services. If an insured person falls sick, he ceases to qualify either for unemployment benefit or for unemployment allowance; he is entitled to sickness benefit, but this takes no account of dependants, and he is therefore frequently driven to apply for poor relief. This is an additional trial to the mind when the body is least able to stand it. Mr. Jones also refers to the absence of anything but poor relief for non-manual workers, such as ships' officers, salesmen and clerical workers who when in work were earning more than £250 a year.

A section on education indicates the difficulties which many teachers in elementary schools in the area have to face as well as the points at which reorganization on the lines of the policy laid down in the Hadow report is most backward. The housing situation is summarized in a further section and particulars of rents and rates are analysed in a final table. The whole handbook, brief as it is, affords an admirable example of the presentation of facts in a manner designed to stimulate appropriate action.

The Highgate Literary and Scientific Institution Centenary Celebration

ONE of the marked features of the intellectual life of the early years of the nineteenth century was the founding of philosophical, literary or scientific institutions, or societies where lectures could be delivered, discussions held and where libraries could be formed and housed. Many of these institutions, especially those in small towns, have disappeared, or parts of their activities have been absorbed either in the local free library, or in the neighbouring technical college.

Some of the societies have survived and are doing most useful work: amongst these may be mentioned the Cambridge Philosophical Society, the Royal Glasgow Philosophical Society, the Manchester Literary and Philosophical Society, the Leeds Philosophical Society, and the Highgate Literary and Scientific Institution, which has just celebrated its centenary.

Exactly one hundred years ago, on January 16, 1839, a meeting was held at the Gate House Tavern, Highgate, to consider the formation of a society, or, in the quaint words of the invitation card, "for the purpose of forming an Institution designed to excite and cultivate an intelligent interest in the objects of literature and science". The first president was Mr. Harry Chester, who served in that capacity for eighteen years. The Society was evidently welcomed by the inhabitants of Highgate, because at the end of a month the president in his first presidential address was able to state that 110 members and associates had been elected, and that four hundred volumes had been placed in the library, of which three hundred were donations.

The founders were determined that the Institution should be democratic, as is shown by the opening remarks of the president: "This is a voluntary Association of many for the benefit of all and open

to all; it is no exclusive Association, to which admission depends on the likes and dislikes of individuals. Here all classes may meet without annoyance to any: and therefore with advantage to all."

In May 1840, the premises the Institution still occupies were rented from the trustees of the estate of Sir John Hawkins, who was an executor, and also a biographer, of Dr. Samuel Johnson. In 1932 it was found possible to purchase the freehold of the property, and in 1936 that of the immediately adjoining property, thus giving the opportunity for further future extensions.

The annual reports of the committee of management of the Institution give a brief story of its activities. In the seventh report (unfortunately, the first six reports are missing) a list of the periodicals in the reading room for the year 1846 is given. It is interesting to note that *Blackwood's*, *Chambers's Journal*, the *Edinburgh Review* and the *Quarterly Review* were mentioned; the remaining periodicals are no longer in existence.

The formation and maintenance of the library has always been regarded as one of the chief duties of the committee of management. The library now consists of more than 11,000 volumes, and includes a considerable number of books of reference. It must be confessed that the scientific side of the library has been allowed to lapse more than it should have done.

The giving of lectures by well-known experts and authorities has always formed an important activity of the Institution. It has been estimated that some 1,700 lectures on the greatest variety of subjects have been given during the past century. Looking back through the annual reports, the development of many of the sciences can be traced by the names of the lecturers and their subjects. "The Proposed Atlantic

Telegraph" (1857), "The Electric Light" (1881), "Polarized Light" (1881) by Mr. William Spottiswoode, then president of the Royal Society, "The Habits of Ants" (1884) by Sir John Lubbock, "Fireworks. Their Chemistry and Mechanics" (1886) by C. V. Boys, "An Evening with the Telescope" (1896) by Sir Robert Ball; and then down to the present time "Large Telescopes" (1937) by the Astronomer Royal, and "Links with the Past in the Plant World" (1938) by Sir Albert Seward. That the artistic and literary side of the Institution has not been neglected may be gathered from the fact that Prof. Henry Morley and Prof. S. R. Gardiner delivered courses of lectures on "Chaucer and the English Writers" and "On the History of England" respectively. Amongst modern writers who have spoken at the Institution may be

mentioned Mr. John Drinkwater, Mr. J. B. Priestley and Sir William Rothenstein.

To commemorate the centenary of the Institution, an appeal has been launched to enable some alterations and additions to be made to the old buildings. At the centenary dinner, held at the Criterion Restaurant on January 16, the president (Mr. R. S. Whipple), replying to the toast of "The Institution", which had been proposed by Sir Ian Fraser, mentioned that the sum of £1,327 had been promised—a good beginning, although much more is required. Sir Robert Waley Cohen proposed the health of the visitors, to which the Mayor of St. Pancras and Prof. Allan Ferguson replied. The latter dwelt on the usefulness of institutions such as that of Highgate as centres of intellectual activity.

Additional Evidence of Early Man in America

FURTHER particulars of the Borax Lake site, Lake County, California, on which relics of the Folsom and the earlier Mohave Lake cultures have been found, are made available in a preliminary report to the Carnegie Institution, Washington, by Mr. M. R. Harrington of the South Western Museum, Los Angeles, who was engaged in exploratory investigation there from July 1937 until June 1938.

The bed of Borax Lake is now dry, except for a little saline water at the north-west end. It is surrounded by hills, 300–400 ft. high; but at the south-east it is separated from the Clear Lake basin by a ridge 100 ft. high only. A number of small canyons drain into the lake bed. Their alluvial fans are insignificant, with one exception, on which is evidence of human occupation over a considerable period going back to a time even before the formation of the fan began.

On the surface, Folsom and Mohave points occurred with other elements of the two cultures, as well as a certain archaic type of stemmed projectile point, now named 'Borax Lake' from its relative abundance. With these were a few modern chipped obsidian points. Excavation revealed abundant artefacts at a depth of five and a half feet in dark-coloured soil, and occasional finds in the underlying yellow gravels, sands and clays to a depth of eight feet. No true Folsom or Mohave points were found below the surface, but 'Silver Lake' points of the Mohave complex, Borax Lake points and a 'willow-leaf' type occurred. A keeled type was abundant in the lower part of the deposit with large scrapers and combined chopper-scrapers. Smaller scrapers appeared practically throughout. Metates, hammer-stones and pestles were found, but no shell or bone implements.

It is suggested that occupation, possibly seasonal, began with the pluvial which followed the Pleistocene ice age, and was abandoned at its close, when desiccation set in.

At the same time exploration and partial excavation of caves in south central Oregon, carried out from 1934 onward by Dr. L. S. Cressman, professor of anthropology in the University of Oregon, would now appear likely to have an important bearing on the date of man's appearance on the American continent. These caves, situated in what is now an extension of the Great Basin of the United States,

were produced by the wave action of glacial lakes formed in dammed valleys during the Pleistocene period. On the recession of the ice and the onsetting of gradual desiccation the lakes disappeared, leaving the caves high and dry. One cave explored, for example, is two hundred feet above the valley floor. The caves were then occupied by man for some considerable time. Dr. Cressman has excavated occupational debris to a depth of nine feet or more.

In a preliminary report, also addressed to the Carnegie Institution, on excavations in 1937 at Catlow Valley and in three other localities, which were supported financially by the Institution, it is stated that numerous artefacts were discovered. These included basketry, sandals and black, undecorated potsherds. Faunal bones indicate a change of diet from mainly waterfowl and small rodents in the lower levels to large mammals, deer, bison and mountain sheep, in the upper.

Of two finds of human skeletal remains, one, consisting of a skull and other parts, was embedded about six inches deep in gravels at the north end of the cave and almost under the rear wall. This was about seven feet below the surface of the cave deposits. Absence of clear stratification in the cave invests this discovery with some ambiguity; but Dr. Cressman inclines to the view that the body was deposited in the gravels by wave action, when it was partially decomposed, but still covered with flesh, thus accounting for the unscratched condition of the bones and the circumstances of deposit. This could have happened only when the lake had begun to fall, but storm waters still invaded the cave, that is, not more than 15,000 years ago. It is, therefore, in Dr. Cressman's view, "entirely likely that we have here a representative of early man in the New World".

In two cave sites, one at Paisley and one at Fort Rock, a layer of pumice overlay the earliest evidence of human occupation. The earlier of these, that at Paisley, is assigned to an age of about 10,000 years.

In view of the abundance of fresh water and game in this early period, Dr. Cressman concludes not only that numerous traces of early man will be found in this area, but also that it may have served as the line of advance to Central America of the Asiatic immigrants.

Science News a Century Ago

Birth of Microphotography

IN his paper to the Royal Society on January 31, 1839, entitled "Some Account of the Art of Photogenic Drawing or the Process by which Natural objects may be made to delineate themselves without the aid of the Artist's pencil", Fox Talbot devoted a section to the application of the art to the microscope. "Contemplating the beautiful picture which the solar microscope produces," he wrote, "the thought struck me whether it might not be possible to cause that image to impress itself upon the paper, and thus to let Nature substitute her own inimitable pencil for the imperfect, tedious and almost hopeless attempt of copying a subject so intricate. My first attempt had no success . . . I therefore began a series of experiments in order to ascertain the influence of various modes of preparation . . . the result of these experiments was the discovery of a mode of preparation greatly superior in sensitivity to what I had originally employed. . . . When a sheet of this, which I call 'Sensitive Paper' is placed in a dark chamber, and the magnified image of some object thrown on it by the solar microscope, after the lapse of perhaps a quarter of an hour the picture is found to be completed. . . . On examining one of these pictures, which I made about three years and a half ago, I find by actual measurement of the picture and the object that the latter is magnified seventeen times in linear diameter and in surface consequently 289 times."

The Rhinoceros in the Paris Basin

IN its column of miscellanea, the *Athenaeum* of February 2, 1839, said: "On digging the foundations of the new buildings at the Hôtel de Ville in Paris, the workmen, at a depth of seventeen feet, in an alluvial yellow sand, mixed with pebbles, found the right humerus of a rhinoceros, named by M. Cuvier *R. Tichorhinus*. Rhinoceros bones have not been before met with in the Paris basin, although the bones of elephants have occurred. The humerus now alluded to is only four lines less than that of the Cape Rhinoceros, in the museum of the Jardin du Roi; it is sixteen lines less in length than the single-horned rhinoceros of India, but its circumference exceeds each by one inch. M. Cuvier's opinion thus appears to be confirmed as to the relative size of the two-horned fossil rhinoceros which he thought was of shorter and thicker proportions than the recent animals."

Preservation of Bodies for Dissection

THE *Lancet* of February 2, 1838, contains the following information: "M. Gannal has recently published a pamphlet on the embalming of bodies and the preservation of specimens of natural history and morbid anatomy. After numerous trials with the salts of alumina and various other substances M. Gannal has elected the sulphate of alumina as being at once the most efficacious and the cheapest material that can be employed. Two pounds of the sulphate of alumina dissolved in a quart of water are sufficient to preserve a dead body in a state of freshness for at least two months. If the weather be very hot it will be necessary to employ the fluid in a greater degree of concentration. The solution of alumina is simply injected into the vessels of the subject, and the cost of preservation does not exceed tenpence for each body."

Societies and Academies

Paris

Academy of Sciences (*C.R.*, 208, 22-56, Jan. 3, 1939).

A. CHEVALIER: Species, varieties and hybrids of cotton, especially the cotton of Asiatic origin cultivated in tropical Africa. These Asiatic cottons are not of commercial importance, having been displaced by American cottons.

F. ENRIQUEZ: The characteristic property of irregular algebraic surfaces.

F. ROGER: Critical varieties of systems of functions of many variables and the critical families in the calculus of variations.

H. MILLOUX: A new inequality in the theory of meromorphic functions.

P. VAILLANT: Passage of current through copper iodide. A cell consisting of 'iodized' copper foils has a conductance of some tenths of mhos, which varies between wide limits with intensity and duration of current and the temperature.

A. RABINERSON and M. PHILIPPOV: Emission of ultra-violet rays in the course of coagulation [of hydrophobic sols such as $\text{Fe}(\text{OH})_3$ and V_2O_5 and of hydrophilic sols such as sodium oleate].

P. CASTEL: Preparation of ortho-arsenic acids of thorium.

C. PRÉVOST: Contribution to the study of the Raman wave numbers of the ethylenic bond.

O. K. HOVO: An α - γ -biethylenic alcohol.

P. GAUHERT: Mobile rings produced in anisotropic drops of the nematic phase by the addition of a substance possessing [optical] rotatory power. The method provides a means of detecting optical rotatory power and its sign; 0.1 mgm. or less of the substance is required.

H. GARRETT: Measurements of radioactivity and temperature in the region of Lyngmarksbreen (northern Greenland).

J.-L. VIDAL: Role of transpiration and of carbon dioxide in the etiology of calcium chlorosis. Although lack of soluble iron may be the fundamental cause of chlorosis, carbon dioxide in the soil and intense transpiration are other factors.

E. MILNE: Influence of altitude on the biology of the potato. Altitude and also the use of artificial cold increase the vitality and productivity.

E.-F. THÉBOINE and MILLE T. DEVRIENT: Degree of oxidation of the waste products of protein catabolism as a function of their importance and of their origin.

MME. S. BELLUO, J. CHAUSSIN, L. LESCOEUR and MME. T. RANSON: Action of Vichy water treatments on the urinary elimination of the normal man; modifications produced in the metabolism of phosphates.

Dublin

Royal Dublin Society, December 13.

V. C. BARRY: Constitution of laminarin: isolation of 2:4:6-trimethylglucopyranose. Attempts made to extract laminarin sulphate from *Laminaria* fronds with dilute oxalic acid gave laminarin which contained very little combined sulphate. Laminarin was converted to a triacetate which on methylation was converted quantitatively to trimethylaminarin. Hydrolysis of trimethylaminarin gave a crystalline trimethylglucose which was identified as 2:4:6-trimethylglucopyranose. Laminarin, therefore, is linked from the aldehydic carbon of one glucose unit to the third carbon of the next unit. Examination of its properties suggests that laminarin consists of a chain of β -glucopyranose units bent into a spiral form.

J. S. BARLIE: A note on the waxy secretion of some glaucous cedar leaves. Two cedars of the same variety, *Cedrus atlantica* var. *glauca*, were compared. One grown in a city atmosphere was very stunted and weakly, being but 1.63 m. high. The other tree, $2\frac{1}{4}$ miles out of town, was well developed and healthy, about 7 m. high. Each tree was more than twenty years old. It was suggested that the stunting of one tree was due to the blocking of the stomata of the leaves by soot; and examination of sections of the leaves by transmitted light indicated that the stomata were occupied with an opaque material, which also covered the surface of the leaves. This substance, however, was seen to be pure white. It gives the whole tree its characteristic silver colour, and was shown to be a wax. It is apparently a normal secretion, for it was found on the healthy as well as the stunted tree.

Tokyo

Imperial Academy (Proc., 14, No. 8, 325-357, November 1938).

HIROKATSU YAHN and TOKIO SHIKAMA: A new Jurassic mammalian from South Manchuria.

Vienna

Academy of Sciences, November 10.

A. KAILAN and O. ALBERT: Velocity of catalysed hydrogenation. The velocity of hydrogenation of aliphatic acids in the presence of a nickel catalyst is determined. Acids with an even number of carbon atoms have a higher velocity of hydrogenation than the neighbouring acids with odd numbers of carbon atoms.

F. WESSLEY and S. WANG: Occurrence of adonitol. The pentahydric alcohol adonitol has been found in the Chinese drug chai-hou (the root of *Duplourum falcatum*). The only other known natural source of this compound is *Adonis vernalis*.

R. WIENER: Radium content of Algae. Both sea- and fresh-water Algae are found to be rich in radium, the content of *Zygnema*, for example, being as great as that of the granites richest in radium. Fresh-water Algae have 10-100 times the radium content of sea-water Algae.

R. PITTIONI and E. PREUSCHEN: Excavations in 1937 and 1938 in the pre-historic mining region of Kelchthal at Kitzbühel.

November 17.

K. GRAFF: Colorimetric measurement of stars down to the $6\frac{1}{2}$ magnitude visible in Europe.

Forthcoming Events

[Meetings marked with an asterisk are open to the public.]

Monday, January 30

BIRKENHEAD COLLEGE CHEMICAL SOCIETY, at 6.—Prof. S. Sugden, F.R.S.: "Neutrons and Chemistry".*

Tuesday, January 31

LONDON SCHOOL OF ECONOMICS, at 5.—Dr. L. Dudley Stamp: "The Fertility of the Land in Britain".*

COURTAULD INSTITUTE OF ART, at 5.30.—Dr. Herbert Chaitley: "Ancient Chinese Astronomy" (succeeding lectures on February 7, 14, 21 and 28).*

Thursday, February 2

INSTITUTE OF ELECTRICAL ENGINEERS, at 5.30.—L. W. Hayes and B. N. MacLarty: "The Empire Service Broadcasting Station at Daventry".

Friday, February 3

GEOLOGISTS' ASSOCIATION (at University College), at 7.30.—E. J. Wayland: "Soil Erosion in Uganda".

ROYAL INSTITUTION, at 9.—Sir Charles Bracey: "Bigger London or Better London".

Saturday, February 4

GILBERT WHITE FELLOWSHIP (in the Hall of the Art-workers Guild, 6 Queen Square, W.C.1), at 3.—Dr. J. Ramsbottom: "Toadstools and Their Ways".

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

UNIVERSITY READER IN BIOCHEMISTRY at Guy's Hospital Medical School—The Academic Registrar, University of London, Senate House, W.C.1 (February 1).

LECTURER IN PHYSICS AND CHEMISTRY AND LECTURER IN ENGINEERING SUBJECTS in the West Hartlepool Technical College—The Chief Education Officer, Education Office, Park Road, West Hartlepool (February 3).

BIOCHEMIST in the Department of Animal Husbandry of the Royal Veterinary College—The Bursar (February 4).

ASSISTANT WOMAN LECTURER IN NATURAL HISTORY in the Froebel Educational Institute Training College for Teachers, Grove House, Roehampton Lane, London, S.W.15—The Principal (February 5).

ASSISTANT (grade III) in the Geological Survey and Museum, Exhibition Road, South Kensington, S.W.7—The Director (February 7).

HEAD OF THE CHEMISTRY DEPARTMENT in the Rutherford Technical College—The Director of Education, City Education Office, Northumberland Road, Newcastle-upon-Tyne (February 11).

LECTURER IN CHEMISTRY in the West Ham Municipal College, Romford Road, Stratford, E.15—The Principal (February 14).

PROFESSOR OF MEDICINE in the University of Otago—The High Commissioner for New Zealand, 415 Strand, London, W.C.2 (March 25).

Freedom of the Universities

WITH what now seems almost prophetic insight, the report of the University Grants Committee in 1936 referred to the special responsibility of the universities of Great Britain, in view of the suppression in the universities of several European and other countries of all independent thought and critical discussion of the principles of government or of the meaning of life, if the Greek tradition of candid and intrepid thinking about the fundamental issues of life is to be preserved for mankind. That responsibility has grown the heavier in the last three years. The area in which freedom of thought and learning is proscribed has grown larger year by year, and further waves of refugees have added to the burden of the Society for the Protection of Science and Learning, and converted what was possibly at first regarded as a temporary into an apparently permanent or perennial task.

There are welcome signs that their responsibility is nobly recognized by the universities of Great Britain. In one practical form it is seen in the support which has been forthcoming from them for the work of the Society for the Protection of Science and Learning. A series of meetings has been arranged for the first week in February in the majority of British academic centres, in which many leading men of science have promised to take part, including Sir William Bragg, Sir Henry Dale, Sir Richard Gregory, Prof. Winifred Cullis, Prof. F. A. E. Crew and others. The Royal Society, in collaboration with the British Academy, is giving a special reception to the academic exiles and those who have been working in their interests on February 7, and on February 10 the evening discourse at the Royal Institution is to be given by Prof. Max Born, one of

the many distinguished men of science who have found refuge in Great Britain.

This practical assistance is of importance not only on the grounds of humanity but also in the interests of learning itself, by enabling those who in the past have made important contributions to knowledge to resume their studies or investigations. Besides this, however, there is a rapidly growing volume of evidence that members of the universities of Great Britain, whether engaged in teaching or administration, are fully alive to the importance of preserving their full freedom of teaching and investigation. In a striking address to the Conference of Education Associations on "The Function of the University", Lord Macmillan asserted that the first essential of a university must be its spirit of intellectual freedom. A university must be the servant of truth, and have no other bondage whether of race, State or creed.

Lord Macmillan put freedom in the very forefront of the life of the university, as it is known in Great Britain. It is the essence of knowledge that it should give freedom to those who pursue it. To seek to impede the free interchange of thought and ideals is the supreme crime. The noblest task which the universities can perform is not only to maintain among ourselves the constant and free pursuit of truth, but also to use every endeavour to spread its light throughout the world, so that it penetrates even to those countries where the universities are subservient to the State.

No less striking were the speeches at the recent degree ceremony when the Duke of Devonshire was installed as Chancellor of the University of Leeds. In welcoming the Chancellor, Mr. B. Moust Jones referred to him as one who, by tradition and conviction, accepted both the universality of

knowledge and the trust imposed upon universities to safeguard the liberty of thought and to defend the free spirit of man. In returning thanks for his election, the Chancellor responded on the same note. Of all the forces working for good in the world, for better understanding between peoples, for liberalism and tolerance in the highest sense of the words, for the spreading of true knowledge, the universities and all that they stand for are, he said, perhaps the most important. They are playing a greater part than ever in the life of the nation and their influence is felt among an increasing proportion of the population. Moreover, without minimizing the importance of the practical and utilitarian work at the universities, or their contribution to technical and commercial progress, a university must be a servant of truth.

In delivering an address at the close of the ceremony, on behalf of the honorary graduates, Lord Baldwin spoke vigorously on the same theme. There are two things, he said, for which a university stands pre-eminently: standards, and truth. The more democratic we become, the more important it is to maintain our standards in literature, in art, in science, in work of all kind. Nothing should for one moment be accepted as first-rate which is in fact second-rate. The second thing is truth, which is particularly important to-day. It is not yet in danger in Great Britain and he hoped it never would be. We never want to see the day when truth is sought merely with the object of proving a case, or history written with that object. Universities must stand and be recognized as seekers for truth with no ulterior motive.

It is a strange commentary on the distance we have travelled in the last ten years that the chancellor of a university should find it pertinent to speak thus emphatically on what a few years ago would have seemed a platitudinous theme, and to find his words so warmly welcomed. Lord Baldwin, moreover, proceeded to point out dangers which in Great Britain might affect, even if indirectly, the maintenance of such standards and the service of truth.

For universities to uphold their trust to-day, as ever, they must be absolutely free and independent, governing themselves and regulating themselves, and never becoming subservient. Among the dangers which may threaten their independence Lord Baldwin referred first to that attending the influence of wealth. In Great Britain it is scarcely a source of danger, for when people give money

to universities, it is not given with the idea of interference, but for use. It is for the universities themselves to decide in what way the gifts shall be expended. While this is generally true, in his recent book "The Social Function of Science" Prof. J. D. Bernal refers to ways in which the freedom of a university may be restrained by conditions attached to grants, and indicates that cases of the withdrawal of donations on political grounds are known to many scientific workers. If universities are to make their full contribution to the life of the community, while their members must be careful not to lend the weight of their names or influence to the support of statements on matters of which they have no special knowledge, it would be disastrous if any such restraint prevented individual members of a university from accepting their responsibilities for playing a part in the life of the community, whether as citizens or as the leaders for which their training and ability fit them. An atmosphere of right thinking and right action is demanded as well as freedom, and this is the more important as the emphasis on the social quality of the university is increased.

The greatest danger, however, which threatens the independence of the universities is one from which Great Britain is fortunately so far free—that of State interference. This we have seen in Europe in our own time, though had we not seen it we could scarcely have believed it. Universities depend more and more on State grants and public money, and this dependence is likely to increase rather than to decrease. The burden of equipment and re-equipment for efficient research is one factor likely to increase the need for State assistance. The more democratic that entry to our universities becomes, and the more widely their importance in training leaders is recognized, the stronger their claims upon the State for assistance. Many of the admirable recommendations, for example, of the recent Conference of the National Union of Students on student health depend largely on State assistance if effect is to be given to them. In spite of this, as Lord Baldwin asserted, the universities must resist to the death, if it ever came, any attempt of a Government department, or of a Government of any shade of opinion, to make gifts conditional on what is taught. In view of what has happened in other countries in recent years, we must be doubly vigilant in safeguarding our own liberties and our own freedom. It is a false optimism to eschew such vigilance because there is no immediate threat, especially in the face

of what is happening elsewhere in the world to-day. Circumstances can easily be visualized in which the threat might become imminent even in Great Britain. Nor is the threat confined to the totalitarian regimes. Even in the western hemisphere, religious dogma has already sought to restrain the teaching of particular scientific theories in the post-War period.

In Great Britain, as has already been pointed out, one or two attempts have been made, if not from the Government side, to impose restraints by withholding donations or subscriptions. When university needs are growing and financial stringency threatens, it is the more important that universities should stand together in resisting such pressure and in exposing the instigators. Such danger as exists is in fact largely indirect. It arises in part from the unfortunate extent to which teaching and research are linked under our present system. Conditions which may quite legitimately be laid down in regard to the donation of a large sum for research are quite intolerable if applied to teaching. None the less, because teaching and research are so interlocked, quite unintentionally endowment of research in this way may affect the prestige or extent of freedom of teaching in a particular subject.

Particularly is this true in the social sciences. On the universities above all lies the responsibility for developing a world conscience and a world culture if mankind is to be turned aside from the hideous road to economic self-sufficiency and war.

Moral unity can only be achieved through mutual understanding, respect and approbation, and we need more than ever to bring into relief the true aim and purpose of human society. Social science in this sense can bring into being a vital relation between the university and the non-academic world, but it can only do so as long as it possesses, unchecked and unhampered, its full liberty of criticism and investigation, free from any suggestion of prejudice or bias.

Many will recall Lord Baldwin's insistence on this same responsibility for preserving freedom and all it involves in the elimination of prejudice and of bias by the maintenance of scrupulous honesty of thought and fairness of criticism, in his welcome to the delegates to the Congress of the Universities of the Empire held at Cambridge three years ago. Scientific workers may be equally grateful for his latest reminder of their obligations and duties in this matter. Contact with many of the refugee scientific workers whom the Society for the Protection of Science and Learning has been assisting should render their own experience available for the vital task of foreseeing the threats to our great heritage of freedom and integrity of thought, and taken in due time, wise measures may be devised to minimize the danger, if not to avert it entirely. Certain it is that freedom is best served to-day by vigilance and foresight and constructive action, rather than by procrastination which may leave us merely with the option of resisting unto death.

French Administration in Africa

African Majesty:

a Record of Refuge at the Court of the King of Bangangté in the French Cameroons. By F. Clement C. Egerton. Pp. xx + 348 + 123 plates. (London: George Routledge and Sons, Ltd., 1938.) 18s net.

MR. EGERTON'S choice of a change of scene to escape certain features of civilized life was little more than fortuitous; but in the event it proved well judged for his purpose. For some months he lived in the headquarters of a native king of the French Mandated Territory of the Cameroons, and came into intimate contact with a cultural outlook and organization of life which he found novel, but in its cultural environment, essentially reasonable, allowance being made for

certain adjustments necessitated by the regulations of the mandatory power.

The author has had the advantage of training under Prof. Malinowski. It is, therefore, scarcely necessary to say that life as he viewed it at the *chefferie* of Bangangté was seen as a whole. The history of this kingship, unlike others enshrined in shorter memories in this part of Africa, is known for some ten generations. The country has been in the possession of the people, immigrants, for not more than a hundred years. In consequence, it is possible to trace to a well-defined origin certain peculiar characters in the social organization, such as, for example, the institution of the chief's henchmen, and the delegation of the chiefly authority to local sub-chieftains. The whole essence of the kingship seems to have resided in

organization for war; but under European control the office would appear to be stripped of its meaning. Yet the present king, probably a forceful personality under a deceptive exterior, in some manner which Mr. Egerton was not able to fathom, has retained his sacrosanctity, even for radically-minded individuals, who did not refrain from criticism, and even regarded any member of the blood-royal as something of a rogue.

Informative as is the author's account of a society largely pagan, his remarks on their character and on French methods of administration, both in relation to future development, are even more illuminating. They are those of a well-balanced and careful observer. His attitude towards the French administration, so far as it goes, is wholly favourable; and while he regrets change in the native, he accepts the fact as inevitable. He maintains, however, that the changes which European control has introduced, in what is intended to be the spirit of the mandate, are advantageous to the white man rather than to the

native. This perhaps is to take a short view. Custom at present, he notes, is preserved under the influence of the members of the community who are more than thirty years of age; but desire for the power, which obviously is inherent in the white man, attracts the native and leads to imitation, which appears to fasten on the less desirable features in white character and culture. The needs of the people of the Cameroons, as the author sees them—he attempts no judgment on Africa as a whole—is for the reinforcement of custom under a strong personal administration, which will ensure, through the co-operation of the chiefs, its compulsory observance. Further, the future of the African, he holds, demands a policy which should not be at the mercy of an uninstructed democracy, or made subservient to European political relations.

Mr. Egerton writes lightly and easily; but no reader of his book should allow himself to be misled into thinking that what he has to say is not deserving of most careful and mature consideration.

The Practice of Plant Propagation

Propagation of Plants:

a Complete Guide for Professional and Amateur Growers of Plants by Seeds, Layers, Grafting and Budding; with Chapters on Nursery and Greenhouse Management. By Prof. M. G. Kains and L. M. McQuesten. Pp. x+555. (New York: Orange Judd Publishing Co. Inc., 1938.) 3.50 dollars.

IN the forefront of programmes of agricultural and horticultural research of the last twenty years have been placed agronomic studies of economic plants; thus extending applied botanical investigations into the yield, in quantity and quality, of these plants. The technique employed in the maintenance and multiplication of such plants has of necessity also been subject to closer scrutiny, although but infrequently forming the major item of the programme at any one station or institution. It is not surprising that a standard text-book written twenty years ago required thorough revision in the light of such newly acquired knowledge. The present authors claim in their preface to have carried out such a revision, and a brief survey of the contents of the volume under review generally substantiates their claim.

The earlier chapters deal with topics related to the establishment in field and garden of many short-lived plants; these include germination studies and methods of seed testing. The Seeds

Act of 1920 and the regulations laid down in 1922 govern the tests made in Great Britain of agricultural seeds and vegetables; whilst seed establishments of high repute test their flower seeds also. Whilst there are differences between the American and British legislation concerned, the technique of seed testing in the two countries is in many respects similar, so that the subject-matter of these chapters is of value to seed analysts and other British readers. Fortunately all the "fifty worst weeds" of the United States (listed as table 15) have not become established in Great Britain.

Recent studies made at the Boyce Thompson Research Institute by Dr. Crocker and his staff have demonstrated the importance of storage conditions in relation to subsequent germination; the value of stratification, ensuring adequate moisture and fluctuating cool temperatures, has been scientifically established. In Great Britain it has been proved with rosaceous seeds that such methods compare very favourably with others, including prolonged colder storage. The table showing the effective temperatures and periods of stratification with many seeds is a valuable feature of the work. In discussing the influence of light upon seed germination, the authors have presented rather a brief list of light-sensitive seed, omitting reference to *Lythrum* and *Primula* species known to be highly sensitive. The germination of orchid seeds receives scant treatment; mycorrhizal fungi

are not mentioned. Mention is made of the fungi causing the 'damping off' of seedlings, and formalin is recommended as a control measure. The widespread use in Great Britain of Cheshunt mixture (prepared from copper sulphate and ammonium carbonate) is evidently not an American practice, but it is one that can be most strongly recommended to American nurserymen and amateur gardeners. The proved value of additional phosphates mixed in the compost after soil sterilization has been clearly demonstrated by Lawrence at the John Innes Institution; other practical points concerning the injurious effect arising from the mixing of chalk or lime with humic matter before sterilization have also been established, but no reference to this work was found in this text.

All manner of vegetative methods of propagation are serially brought under review, and there can be little doubt that the many illustrations in this section will assist students, and more especially those who cannot regularly carry out the operations so clearly described. From the Dutch growers and their research stations information regarding hyacinth propagation has been freely drawn upon; the methods of the late Dr. Griffiths and his associates used in the propagation of lilies from bulbils and scales are briefly described. More recent research comes under review in the chapters dealing with the propagation by stem cuttings. The use of several synthetic growth substances in accelerating and facilitating root development is dealt with, and in this section the authors have

reviewed the work of Dr. Zimmerman and his associates in the United States, and that of investigators in Great Britain.

In the section dealing with the control of pests, a useful practical point concerning eelworm infection of herbaceous phlox might be added to a later edition; from root cuttings non-infected plants are readily raised, as is a Wisley practice, whilst stem cuttings remain infected.

When reading of the propagation of fruit trees, and methods of grafting and the after treatment of grafted trees, and particularly (Chapter xiv) when considering fruit tree stocks and the influence of stock on scion and the reverse processes, the value of the book would have been enhanced for British readers had the authors considered in further detail East Malling work upon the classification of apple stocks and the influence the various types exert; reference is, however, made to certain effects of root-stocks on the blossoming of seedling apples. The authors deal with citrus stocks, and other trees not grown to any large extent in Great Britain.

The modern tendency towards mechanization is seen in the illustrations and descriptions of machinery used in nursery management. The American Quarantine Act and the regulations appertaining to this Act come under review. The book concludes with a series of fifty "practicums" or schedules for practical work. The selected bibliography refers to 150 titles of recent publications.

M. A. H. TINKER.

Soil Conservation

Conservation of the Soil

By Prof. A. F. Gustafson. (McGraw-Hill Publications in the Agricultural and Botanical Sciences.) Pp. xvii+312. (New York and London: McGraw-Hill Book Co., Inc., 1937.) 18s.

Crop Management and Soil Conservation

By Joseph F. Cox and Dr. Lyman E. Jackson. (Wiley Farm Series.) Pp. xvii+610. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1937.) 13s. 6d. net.

SOIL conservation is as old as, and might indeed be regarded as synonymous with, agriculture. Ancient China, India and Persia knew about it, but during the last century, while great advances have been made in the art of soil exploitation to satisfy the needs of rapidly expanding populations, little attention has been paid to soil conservation, with the result that soil fertility has declined

catastrophically and soil erosion has become almost universal. The consequences have been particularly disastrous in the United States, where the imperative necessity of putting back into the soil what pioneer farming took from it is now realized. At the present time, American agriculture is undergoing a fundamental and timely revolution, from which an art, as old as China and as new as the United States, will in due course emerge.

Prof. Gustafson gives a very clear account of the main principles of soil conservation. Little that the ancients did not know and practise has emerged during the renaissance of conservative agriculture, but ancient customs have been greatly modified to suit modern large-scale farming carried out with powerful instruments of destruction. Forests and prairies which under exploitative agriculture were regarded as inefficient forms of land utilization have earned renewed respect as far more efficient soil

conservers and flood controllers than any structure built by man. The evolution of the broad-based from the bench terrace as an efficient instrument for retaining water and soil, while not interfering with mechanized agriculture, is the most original feature of the new soil conservation. Listing, silt-pitting, strip-cropping, rotations are all modifications of ancient practices designed to curb the destructiveness of mechanized cultivation. Conservation of forest land consists essentially in managing the forest on a sustained-yield basis—a practice which comes naturally enough to the real forester but is something of an unwelcome innovation to the lumber baron. In short, the art of soil conservation is to treat the soil kindly, and its practice involves moderation in the use of already existing scientific equipment rather than the application of more science.

Science, however, can take a hand in flood control in badly eroded catchment areas where a highly specialized engineering technique is demanded; but even there it is now recognized that the engineer performs the surgeon's task of keeping the battered patient alive until Nature can complete a lasting cure with trees and grasses. An interesting application of meteorological data is the use of rainfall-intensity frequency charts in determining the design of flood-protection constructions.

"Crop Management and Soil Conservation" is a college text-book of conservation agriculture. The first part emphasizes the need for caution on the same lines as Gustafson describes, the second part tells the student how to farm for a living and possibly also for a profit. It is a straightforward guide to sound American farming. G. V. J.

More Chemical Encyclopædia

Thorpe's Dictionary of Applied Chemistry
By Prof. Jocelyn Field Thorpe and Dr. M. A. Whiteley. Fourth edition. Vol. 2: B1—Chemical Analysis. Pp. xxiii+712. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1938.) 63s. net.

THE second volume of Thorpe's "Dictionary" has made its appearance with commendable punctuality. In a foreword, the editors state that they have done their utmost to reduce the space occupied by organic formulæ, although they maintain, quite rightly, that a modern article on organic chemistry must be illustrated by elaborate formulæ. How much more, however, should an article on an industrial process be illustrated by elaborate drawings of plant? Yet these are mainly conspicuous by their scarcity. The new special drawings promised in the foreword appear to be about eleven in number and, of these, eight are small and purely diagrammatic. A cement kiln is allotted far less space than the six formulæ for cedrene and its derivatives, and many of the photographs give no useful information. The outstanding exception is the article on bromine, with ten good drawings reproduced from the Supplement.

The unfortunate choice of the same type for formulæ and the headings of the articles frequently makes it difficult to find a subject, particularly as no spacing is allowed between the end of one article and the beginning of the next, and confusion in reading is caused by the somewhat unusual practice of continuing the subject matter

of the first column in the second whenever a table intervenes which reaches across the page.

The greatest defect of the work is perhaps the lack of any kind of index, without which much useful material is bound to escape unnoticed. A brief list of the more important items which do not appear alphabetically under their own headings would take less time to compile than the thirteen-page list of abbreviations of the titles of journals and could be carried on from volume to volume.

The longer articles, largely written by men engaged in industry, are for the most part excellent, although, as is perhaps inevitable, there tends to be a lack of correlation between the number of pages devoted to a subject and its importance—for example, 14½ pages to rice and 2½ to wheat. In a few cases, there is a scarcity of references later than 1930, and an article on chemical affinity, in which 'activity' is scarcely mentioned and 'free energy' not at all, is unusual in 1938. Among much good matter, it is perhaps invidious to select individual contributions, but mention must be made of those on bromine, synthetic camphor, carboic acid, carbon dioxide, carbon disulphide, casein, celluloid, celluloid plastics (photographic film) and cellulose. All these abound with details which are not readily to be found elsewhere and inspire a feeling of reality.

The shorter items are, as in earlier volumes, clear and concise summaries, with references which form a useful starting point for further investigation. It is not quite clear why some of the halides and sulphides of carbon should have been grouped with phosgene under the heading "Compounds of

Carbon", while carbon tetrachloride and carbon disulphide are treated separately and the technically important dichlorodifluoromethane is omitted altogether. The avoidance of such grouping would materially assist the reader.

The article, "Chemical Analysis", deserves special mention. It is no mean feat to give a fairly detailed account of most of the branches of this subject in the space of 170 pages, but yet it is impossible to resist the feeling that the effort is largely wasted. The first fourteen pages are a paraphrase of the corresponding portion in the 1912 Dictionary, and seem to have been included owing to their historical interest. It does not appear possible otherwise to explain the poorly drawn and inaccurate illustrations, or the advice to fill a steam oven with toluene and to avoid the use of coal gas when making dry tests for sulphur. Electrically heated ovens and the many modern aids to analysis are barely mentioned.

The remainder of the article contains information to be found in most text-books on analysis, but frequently not in sufficient detail to enable an analysis to be conducted without further reference. Many of the interesting new reactions described in the Supplement have been omitted. One of the difficulties confronting the modern analyst is to decide which of several procedures to adopt, but in this respect no assistance is forthcoming. A recommendation by the authors of one particular method would have been more valuable than details of several.

From the reader's point of view, it would have

been advantageous to have limited the scope of the article to general and novel methods, leaving further details to be presented under the headings of individual elements. Aluminium, for example, is to be found under "Cobalt Nitrate Reactions", "Special Reactions", "Drop Reactions", "Beryllium", "Aluminium" (with instructions to heat alumina to 1,200° in a sintered glass crucible), "Volumetric Analysis" and "Colorimetric Analysis", in striking contrast to the convenient and admirable summary given under "Aluminium" and noticed in a previous review. The search for an analytical method is not facilitated by the absence of sub-titles at the head of the pages or by the arrangement of the elements in chemical groups for the first hundred pages in contrast to the alphabetical method adopted for the rest. The former is perhaps more scientific, but it is more difficult for the reader who may not have the Periodic Table at his finger tips and may wonder why "uric acid" should be placed next to "silicon".

Only ten pages are devoted to physical methods. The writer on "dielectric constant" (presumably, as an analytical method) has been unable to refrain from a digression into dipole moments, and it is a pity that space could not be found for a table of *raies ultimes* in the excellent account of the analytical applications of spectroscopy.

It cannot be denied that this is an interesting and valuable book. Whether it is worth while for those who already possess the last edition and supplements to purchase the volume is a matter for individual decision.

Structural Evolution of Southern California

Structural Evolution of Southern California

By R. D. Reed and J. S. Hollister. Pp. xx+157. (Tulsa, Okla.: American Association of Petroleum Geologists; London: Thomas Murby and Co., 1936.) 2 dollars; 9s.

THE problem of structure of the Coast Ranges of California is by no means new. In fact, ever since the middle of the last century, when the first geological expedition went to California, it has been a subject of interest. Since the discovery of oil in Southern California, this interest in structural complexities has naturally been considerably enhanced. As a result, the State Mining Bureau and the United States Geological Survey have sponsored a great deal of survey work in this territory. Nearly the whole of Southern California has been mapped in detail, and widely differing theories on structure have been advanced

from time to time, many of which have been published.

R. D. Reed and J. S. Hollister, in the book under notice (in a sense a sequel to "Geology of California" wherein only casual reference was made to structural evolution), have made use of all published bulletins, papers, maps, charts, etc., available to them. No claim is made that all the opinions expressed are original. Their work has rather been the collection, correlation and sifting of all data, and an expression of views they have come to believe as a result of this spade-work.

On the problem of essential structure, the authors are impressed with the belief that post-Jurassic structural evolution has been dominated by distribution of fundamental basement types. Distribution of these types indicates that Southern California was divided in Lower Mesozoic times into six major palaeogeographical provinces;

accordingly, names have been adopted or invented for these provinces. The important "Franciscan" deposits appear to have accumulated in typical geosynclines and therefore their underlying "provinces" are designated geosynclines. Contiguous "positive" provinces are given names ending in "ia" as being comparable with hypothetical ancient lands such as "Appalachia" and "Cascadia".

The conclusion is reached that a local orogenic time-law holds good for provinces similar to one another in basement character; "... so far as the post-Franciscan history of Southern California is concerned, tectonically comparable areas seem to have been affected at all times by orogenic and epeirogenic forces". Were other regions of similar size and complexity to Southern California classified by the same geologist into tectonic belts, and a sequence of tectonic events for each belt and for the region as a whole worked out, this local orogenic time-law might be more extensively

generalized. Decision on this point, however, must necessarily be delayed for some time to come, owing to the volume of work involved.

The above is only one of many interesting suggestions put forward as a stimulus to further investigation of this fascinating problem. Actually Southern California is too small an area to throw much light on major structural problems concerning comparable world-wide tectonic movements, but the results achieved by systematic assembling of data necessary for rational theorizing on Coast Range structure must prove of great interest to those concerned with major geotectonic problems.

The authors are to be congratulated on a text which lifts mere compilation of data to a high plane of scientific interpretation and constructive philosophy. A modest ending, suggesting that every reader may be "inspired to invent better theories for himself and will readily succeed", only serves to sustain the reader's confidence in the soundness of the authors' thesis.

Cellulose

(1) An Introduction to the Chemistry of Cellulose

By J. T. Marsh and Dr. F. C. Wood. Pp. xv + 432 + 18 plates. (London: Chapman and Hall, Ltd., 1938.) 21s. net.

(2) Die Chemie der Cellulose:

unter besonderer Berücksichtigung der Spinnfaser- und Zellstoff-Industrien. Von Prof. Dr. Carl G. Schwalbe. Zweite völlig umgearbeitete Auflage. Hälfte 1, Abteilung 1: Die Chemie der Hölzer. Pp. viii + 451. (Berlin: Gebrüder Borntraeger, 1938.) 24 gold marks.

CELLULOSE, the structural basis of the vegetable world and the raw material of the cotton textile industry, has long been the subject of scientific investigation. Within comparatively recent years its chemical constitution, in particular the length of the chain molecule, has been approximately determined, though the view is gaining ground that the properties of normal cellulose only reflect the average characteristics of the ultimate units of cellulose of which it is composed.

The industries which concern cellulose are so numerous and in many respects so different the one from the other that those engaged in them have a variety of problems to study. Nevertheless a good general knowledge of the behaviour of cellulose is the first requisite, and the progress of the last few years, both on the scientific side and

in regard to practical application, has enabled a considerable number of facts to be established, including physical data, which will facilitate further attack on the riddle presented by this most remarkable of all natural materials.

(1) This book is sponsored by Sir Kenneth Lee, who affirms that the close correlation of science to the textile industry has already had a profound effect on its development. The authors claim it to be a relatively simple book which may act as a guide to chemists engaged in the cellulose industries. The scope is best judged from the chapter headings—general properties, dispersed cellulose, modified cellulose, cellulose derivatives, constitution and structure. Being intended for experts, it is scarcely readable in the ordinary sense; but is full of informative detail. It cannot fail to be useful, more particularly since the literature of the subject is widely scattered, often in journals which are not everywhere available.

(2) Dr. Schwalbe wrote an important book on cellulose in 1911 which was very rapidly taken up. Various reasons have delayed the production of a second edition until he has retired from active work. A comprehensive text-book of the whole subject in the old German style is now planned in four volumes of which this, the first, deals with wood alone. For those primarily interested it will no doubt be found exhaustive, though, to judge from the references, very little British work has been considered.

Geology of the Tampico Region, Mexico

By John M. Muir. Pp. xix+280+16 plates. (Tulsa, Okla.: American Association of Petroleum Geologists; London: Thomas Murby and Co., 1936.) 19s. 6d.

KNOWLEDGE of the geology of the Tampico region of Mexico has been gradually amassed over a period of years by geologists and others interested in the development of its oil resources. In 1928, an attempt was begun to collect and correlate information from various fields and this work proceeded intermittently until 1934, when it was decided by the Executive Committee of the American Association of Petroleum Geologists that the results should be published in a separate volume. When it is realized that hitherto no attempt had been made to assemble and present in book form existing knowledge of the geology of that region, it will not be difficult to assess the value of this work, particularly to future workers in the oilfields.

The first half of the book is concerned with stratigraphy and paleogeography of the region. Rocks outcropping in the Tampico Embayment range in age from Middle Cretaceous to Miocene, while beyond its northern and southern limits Paleozoic and Jurassic rocks are found. Descriptions of all the formations encountered are given in considerable detail. The latter half of the book is devoted to an account of structural features of the northern oilfields situated on the southern prolongation of the Sierra Tamaulipas anticline and the Southern Oilfields which extend from about 48 to 90 miles south of Tampico. Main occurrences of oil are described and attention directed to particular characteristics of individual pools caused not only by structural differences but also in most cases by slight facies-changes in the sediments. Throughout the major period of exploitation the southern fields were considered economically to be of far greater importance than the northern fields, but since 1933 this assessment has been reversed. In the appendixes valuable data are given on oilfield temperatures, well pressures, their stripping, shooting and acid treatment. Finally, there is an excellent bibliography of Mexican oilfield geology which, together with the text of the book, forms a useful record of the advancement of geological knowledge in this region during recent years.

The History of the Telephone in the United Kingdom
By F. G. C. Baldwin. Cheaper edition. Pp. xxvi+728+75 plates. (London: Chapman and Hall, Ltd., 1938.) 15s. net.

THE reprint of this history is the same as the first edition of 1925, but it may usefully be recalled that the author brings together representative material relevant to the development of the telephone service in Great Britain from the invention of the telephone more than sixty years ago until 1912, when the main body of the telephone system was brought under the unified control of the State, with details of machine-switching and long-distance telephony up to 1922, which preceded the inauguration of unified control of international telephony by a consultative committee. The author, sponsored by

Mr. Frank Gill, chief engineer of the National Telephone Company between 1902 and 1913, modestly claims that he has prevented historical material from straying, but he has certainly anticipated what he expects a later writer to do, critically to describe the problems of exploitation of an invention in many respects still similar in essentials to its original form, and draw lessons from a balanced view of the past.

Telephony in Great Britain was from the first parochially conceived, harshly restricted by legislation, and hidebound by patents; can we or can we not blame the powers that were for not realising that telephony was to become a powerful public service and treating it accordingly? A parallel history could be written around the supply and distribution of electric power, which is yet to be straightened out. The present rapid increase, as compared with other countries, in both the use of telephony and the consumption of electric power, can be traced to our backwardness following early restriction. That history can teach lessons to authorities is illustrated by the fact that the present radio-relay services are to be taken out of the hands of private companies in the next year or so, before their development gets out of control. L. E. O. H.

Adventures with Living Things:

a General Biology. By Elsiebeth Kroeber and Walter H. Wolff. Pp. xiii+798. (Boston, New York and Chicago: D. C. Heath and Co.; London: George G. Harrap and Co., Ltd., 1938.) 1.96 dollars.

THE teaching of biology is still in the experimental stage in Great Britain; and, as shown by the large number of good American texts on the subject, there is much to be learned from the methods adopted in other countries, especially the United States. The book under review is a case in point. For in it, a wide, though general, survey of the plant and animal kingdoms is made, the 'type system' is disregarded, and there is no suspicion of dividing the subject into the two sections, botany and zoology. Most authoritative surveys and reports on the teaching of biology, including the recently issued report of the Spens Committee, are agreed that the best approach to the subject is through natural history: and this is the method adopted in this book. The authors have shown breadth of vision, and their text is supported by nearly five hundred excellent illustrations, mostly photographs—which are desirable in the early stages of teaching.

Part 1 approaches the subject through natural history, and is a descriptive account of living things. Part 2 is the functional approach, and deals with the way organisms live and reproduce. Part 3 considers the great generalizations of biology, such as unity in organisms, heredity, evolution and human betterment through biology.

The scientific attitude is inculcated and the scientific method adopted throughout by periodic insertions of practical work, problems for class discussion, supplementary activities for the biological novice and bibliography.

The book can be recommended as a guide to the teaching of biology in Great Britain.

Forest Protection

By Prof. Ralph O. Hawley. Pp. ix+262. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1937.) 13s. 6d. net.

THIS book consists of part of the material originally included in the author's "Practice of Silviculture" considerably extended. To some extent, the outline follows European standard works. A notable departure, which in connexion with the United States is readily comprehensible, is that something near one half (117 out of 247 pages) of the book (Chapters viii-xiii) is devoted to forest fires, their suppression, control and so forth.

In the minds of some American authors, there would appear to be doubt as to the borderlands separating different branches of forestry science. It is, of course, obvious that to a varying degree they must run the one into the other. It is therefore all the more necessary that the writers of text-books should reach as clear an understanding as possible in this matter.

Surely since the work in question is entitled "Forest Protection" it was unnecessary for the author to write in his preface "This book is not intended to be an engineering or administrative manual for any of the phases of forest protection". The trained forester will understand the meaning underlying these words, but in the case of a book for the student of forestry they appear out of place.

The book is not illustrated. It is to be hoped that in a subsequent edition the author will supply this want since illustrations are almost essential for the student.

A Text Book of the Differential Calculus

By S. Mitra and G. K. Dutt. Pp. xiv+302. (Cambridge: W. Heffer and Sons, Ltd., 1937.) 10s. net.

THIS book has been written to supply the special needs of teachers and students in Indian universities. The authors have aimed at making the subject clear to the ordinary reader equipped only with an elementary knowledge of algebra and trigonometry. The foundation is well laid in the early chapters, which are devoted to a full and lucid discussion of variables, bounds, limits, continuity and infinitesimals. This part may provide rather stiff reading for beginners; but the time spent on it will, as the authors point out, "lead to a much better comprehension of the essential principles of the calculus". There follows a rigorous development of the standard results connected with the differentiation of functions of a single variable, leading to a consideration of the chief properties of infinite series and their convergence, maxima and minima, implicit functions and changes of variables. The latter part of the course is devoted mainly to the applications of the principles of the differential calculus to geometry, and, in the selection of the examples, a careful consideration has been given to the needs of students not only of pure mathematics, but also of engineering and the natural sciences.

The text throughout is rigorous, lucid and up to

date and is well illustrated both by clearly drawn diagrams and skilfully chosen exercises.

Exposés de Physique atomique expérimentale

6: Spectrographie de Masse; les Isotopes et leurs Masses. Par Louis Cartan. (Actualités scientifiques et industrielles, 560.) Pp. 91. (Paris: Hermann et Cie., 1937.) 20 francs.

THE author's own researches in the field covered by this volume enable him to discuss with both brevity and thoroughness the technique and results of the new spectrometry and to show their bearing on such questions as the energy and stability of the nucleus. The first part treats of the masses and the methods and instruments used in measuring them, from that of Aston of 1927 to the double-focusing ones of the present day. The second deals with isotopes, including those of artificial radioactive substances, their detection and measurement, and the third with the principal numerical relations, such as that of the mass to the charge of the nucleus, and the even and odd law, which have been discovered among the 260 isotopes at present known. The volume is well supplied with plates, figures, numerical tables of results, and a bibliography brought well down into 1937.

Physics for Technical Students in Colleges and Universities

By Prof. William Ballantyne Anderson. Third edition. Pp. xi+807. (New York and London: McGraw-Hill Book Co., Inc., 1937.) 24s.

THIS is the third edition of the author's book and shows the result of long teaching experience in American colleges. The entire manuscript of the new edition has been carefully revised by the author and his engineering colleagues; and many new diagrams and problems have been introduced. The superiority of the metric system is recognized, but the British engineering system, in which the 'slug' is the unit of mass, is frequently used and is recommended to students. It may be pointed out that Henry Cavendish, who weighed the earth, was a younger son of Lord Charles Cavendish, and is not correctly described as 'Lord Cavendish'. The chapters on rotary motion and on uniform circular motion deserve special commendation, and the whole book should serve its purpose admirably.

Handbuch der biologischen Arbeitsmethoden

Herausgegeben von Prof. Dr. Emil Abderhalden. Lieferung 467. Abt. 5: Methoden zum Studium der Funktionen der einzelnen Organe des tierischen Organismus, Teil 10, Heft 7. Allgemeine und vergleichende Physiologie. Pp. 1235-1474. (Berlin und Wien: Urban und Schwarzenberg, 1938.) 13 gold marks.

THIS section contains articles on light-sources for physiological purposes and on methods of measuring and recording electrical changes by M. Wreschner, on the mechanical disintegration of tissues by M. Behrens and on chromatographic analysis by A. Winterstein.

The Swanscombe Skull*

IN view of the importance of the discovery in 1935 and 1936 by Mr. Alvan T. Marston of two bones of a human skull, associated with implements of Acheulean type, in Pleistocene gravels of the Barnfield pit, near Swanscombe, Kent (see NATURE of October 19, 1935, p. 637, and August 1, 1936, p. 200), a research committee was appointed by the Royal Anthropological Institute in 1937 to examine and report on the discovery in all its aspects. Further excavation was carried out on behalf of the Committee by Dr. M. Aylwin Cotton of the Institute of Archaeology, the cost being borne by a grant of £50 made by the Council of the Royal Society. Publication of the report has been assisted by the Trustees of the British Museum.

The findings of the Committee are based upon reports by specialist members of the Committee, which appear as chapters, ten in number, in the report, and following a general description of the site, deal respectively with geology, palaeontology, archaeology, including an account of the further excavations contributed by Dr. Cotton, correlation of the deposits, the general features of the bones, their form, and the endocranial of the brain.

The Barnfield pit, which is situated about half a mile to the north-west of Swanscombe, between Dartford and Gravesend, has long been famous as a rich source of the implements of palaeolithic man and of the remains of Pleistocene mammals; but no human skeletal remains had been found previously. This is also the first occasion on which human remains have been found definitely in association with an Acheulean industry not only in Britain, but in Europe generally.

The deposits belong to the Boyn Hill or 100-ft. terrace of the Thames. A uniform stratification makes it possible to recognize local sub-divisions, in sequence from above downward, of upper gravel and hill wash, upper loam, middle gravel and sands, lower loam, and lower gravel. The deposits lie in a channel, running from west to east, cut in the chalk and Thanet Sands. A subsidiary channel, or possibly scour, containing false-bedded gravel, has cut down through the lower middle gravels through the lower loam to the lower gravel. The two cranial fragments were discovered in an obliquely bedded gravel in this subsidiary channel. This seam is the lowest member in a series of eight similar seams between

the lower middle gravel and the upper middle gravel series. The bones are unquestionably indigenous to the series.

The fossil mammalian remains, of which the examination by Mr. M. A. C. Hinton is not yet complete, include, according to a tentative identification, *Elephas antiquus*, *Rhinoceros hemitoechus*, *Bos primigenius*, *Dama clactoniana*—a species at present known only from Britain—and *Equus caballus*—a fauna predominantly of a woodland type, and of an interglacial facies.

A report on the stone industries by Mr. C. F. C. Hawkes, with the co-operation of Dr. K. P. Oakley and Mr. S. Hazzledine Warren, enters into a detailed analysis of the content of each stratum. This analysis is of importance not only as fixing definitely the place in the cultural series of the implements associated with the human remains, but also for its examination of the attribution suggested by Mr. Marston of the industries of the lower and lower middle gravels to the Challean, or Abbevillian industry, as it is now termed.

The cultural succession, as determined by the report, definitely rules out the Abbevillian attribution, assigning the industry of the lower gravels to Clactonian II, but somewhat prior to Clactonian II of the type site. The lower loam is sterile, such implements as it contains showing evidence of exposure, and evidently having sunk through. The industry is still Clactonian, though of a somewhat more advanced type than that of the lower gravels. The industry of the lower middle gravels is characterized by the number of hand-axes. It was formerly (1912) denominated "Chelles or a transition to St. Acheul"; but it is here assigned to Early Middle Acheulean, the Acheulean III of Breuil; while the large number of flakes may be classed as flake-products of the same Acheulean industry. A small proportion utilized still represent the Clactonian tradition.

Mr. Marston here also assigned certain of the hand-axes to the Abbevillian on the ground of the crudity of their workmanship; but it is pointed out that crudity is not necessarily an indication of relative age, and that the industry must be taken as a whole, when its essential unity appears as entirely of the Early Middle Acheulean.

The industry associated with the skull fragments is regarded as belonging to exactly the same culture as that from the lower gravels. Above the oblique seams of gravel, in which the seam containing the skull fragments is the lowest, the channel is filled by a stratum of gravelly silt, over

* Report on the Swanscombe Skull prepared by the Swanscombe Committee of the Royal Anthropological Institute. Reprinted from the *Journal of the Royal Anthropological Institute*, 68, 1, 1938. Pp. 17-96 + 6 plates.

which the upper middle gravel series continues in the form of horizontally bedded yellow sands, covering the channel and the lower middle gravel surface flanking it. These deposits are not rich in implements, and nothing suggesting an advance in human material culture has been recovered from them. The yellow sands are uniformly sterile and the skull layer is thus well insulated against conflation with any subsequent cultural development. This is reinforced by the upper loam which again is sterile; and only from the top surface have any further implements been obtained. Such flakes and hand-axes as are yielded by the upper loam show that at this stage the culture prevalent at Swanscombe was still Acheulean. Some advance is suggested by 'sub-cordate' or 'sub-ovate' types; but they have never yet been found *in situ* in the Barnfield pit. A sign of real innovation are the primitive 'tortoise' cores associated with hand-axes in Rickson's pit, in which the earliest stage of the Levallois industry has been recognized. The whole evidence from the overlying strata confirms the inviolable association of the skull with a pure Early Middle Acheulean industry, which already, on the evidence of the artefacts alone, had been assessed by Breuil as Acheulean III.

Dr. K. P. Oakley discusses the correlation of the deposits. The gravels of the 100 ft. terrace must be diagnosed as interglacial and as younger than the Lower Chalky Boulder Clay. This is

supported by the fauna and the glacial erratics. From the geological and archaeological evidence no doubt can arise that the middle gravels are older than the main Combe Rock stage. If the industries correspond with Middle Acheulean III, in the Somme Valley Middle Acheulean is assigned to the Mindel-Riss interglacial, and it would seem that the middle gravels at Swanscombe must also be regarded as belonging to that period.

The anatomical and anthropological characters of the skull have been examined by Prof. W. E. Le Gros Clark and Dr. G. M. Morant. The fragments found are the occipital and left parietal. Both are nearly complete and articulate perfectly. The individual to whom the bones belonged was probably female and died in her early twenties. In two respects only do they show any significant difference from a modern skull of *Homo sapiens*, namely, in the unusual breadth of the occipital bone and in the thickness of the bone. The endocranial cast shows no feature which serves to differentiate it from the endocranial cast of modern human skulls. The series of measurements fall well within the range of the modern human female skull. The estimated cephalic index is in the neighbourhood of 78 and the cranial capacity 1,325 c.c., which would be unexceptionable in a modern female skull. The missing parts of the skull, however, might have been so formed as to provide clear evidence of differentiation from modern man.

McDougall's Experiments on the Inheritance of Acquired Habits

IN a series of papers extending over a period from 1926 until 1938, Prof. William McDougall brought together evidence which led him to suppose that the hypothesis of Lamarck concerning the inheritability of acquired characteristics is substantially correct.

In designing his experiments, McDougall kept in mind two principles which previous investigators have overlooked. These are, first, that "the adaptation investigated should be achieved by the intelligent purposive efforts of the organism concerned", and, second, that it should be of such a nature that slight degrees of adaptation should be measurable, for it has already been shown by Lamarck's opponents that acquired characteristics are not transmitted as "perfected wholes of structure or function". Hence, if Lamarckian transmission is to be found at all, it should be looked for as some "slight increase of facility in the acquisition of the modification acquired by the parent". Many generations would

probably be necessary, therefore, before any very marked changes appeared.

White rats were chosen as subjects for this experiment since it was possible to obtain an initially pure strain (Wistar), and since the breeding habits of rats allow a large number of generations to be studied in a reasonable length of time. A preliminary experiment showed deterioration in performance with successive generations, due, apparently, to an increasing fear of electric shock. The final form of the experiment, therefore, was designed to develop such a phobia. To this end, an apparatus was constructed consisting of three parallel alleys, the central one serving as an entrance and the outside ones as exits to a platform. The apparatus was filled with water, and the motivation was escape from the water to a dry platform. Of the two exit alleys, one, the shocked pathway, was brightly illuminated while the other, the free pathway, was kept dim. The task confronting the animals, therefore, was to escape from the water

through the dim alley, the 'error' of choosing the bright being punished by an electric shock of tetanizing strength. The strength of the shock was varied from animal to animal to obtain this behavioural effect with all of them, and tetanization lasted for three seconds. To avoid position habits, the 'correct' alley was alternated from left to right of the central. This alternation technique, however, allows no control of any alternation habits adopted by the rats. Rats were placed in the apparatus in batches of about six at a time and were given six trials daily. The primary measure of any Lamarckian inheritance was the total number of errors made in reaching a criterion of mastery of twelve successive errorless trials, though note was also taken of any pre-training preference for the dim path.

McDougall's conclusions rest, in the main, on the results obtained with three groups of rats, an experimental group (or Tank group), a control group, and an experimental group obtained by adverse selection from the control stock. The Tank rats were originally obtained from Wistar stock, and subsequent generations were obtained by mating trained members of this stock according to a random selection. The only conscious selection of breeding stock was in the rejection of obvious runts. The control stock does not show the same continuity and inbreeding. McDougall's early intention was to use half the original Wistar stock as controls and breed from members trained in some task other than that of the experimental group. This stock, however, seems to have been abandoned, and subsequent controls were obtained direct from the Wistar Institute, or, in some cases, from other laboratories. The adversely selected experimental group represents an attempt to balance any unconscious favourable selection in the Tank rats by breeding from the worst animals in each generation.

The results with the Tank rats show a progressive improvement from generation to generation, until by the thirty-fourth, the average total number of errors per rat had decreased from an estimated 120 for the first generation (McDougall's records are incomplete before the fourteenth), to 36 for the thirty-fourth. This improvement in error scores seems to be correlated with an increase in timidity, cautiousness or hesitancy. 'Normal' learning shows an initial period of rapid, chance reactions, followed by a pre-solution period of hesitancy with oscillations from one exit to the other. This hesitancy developed earlier in the training period with successive generations of Tank trained rats, and is regarded as the probable cause of the decrease in errors. The adversely selected stock similarly show a very marked improvement, the total average error decreasing from 215 to 43

in fourteen generations. However, the control groups also show a decrease in errors. Groups obtained from Wistar stock in 1926, 1927, 1930 and 1932 show a decrease from 149 to 102. Admittedly, this decrease is by no means as large as those of the experimental groups, but neither the number of generations tested nor the environmental conditions of the groups are at all comparable. McDougall interprets the improvement in the control groups, which had had little contact with his laboratory and whose only relation with the experimental groups was that they too were Wistar rats, as indicating a probable improvement in the entire Wistar stock, for reasons which he is unable to suggest. The possibility that there was an improvement in his experimental technique should also be taken into account.

McDougall's experiments have been repeated by Crew and Agar, neither of whom have obtained any evidence of Lamarckian inheritance. Both these experimenters have attempted to duplicate McDougall's apparatus, but have changed the procedures somewhat to obtain what they consider to be more trustworthy results. Thus, Agar standardized the strength and duration of the shock, and abandoned McDougall's group method of experimenting in favour of the more usual individual trials. Crew, on the other hand, retained the group method and used McDougall's tetanizing criterion of the strength of shock, but introduced marked changes in training, giving his animals a hundred trials before the introduction of shock instead of McDougall's six. All these changes, however, though likely to produce marked changes in the rate of learning of any given group of rats, should be relatively unimportant in producing different rates of learning in successive generations, provided the same technique is rigidly adhered to throughout any given experiment.

Explanations of McDougall's results as due to variations in the strength of shock used imply a gradually increasing strength with successive generations. Since there is no evidence either that such a gradual increase did take place, or that the rate of learning is affected by such small variations as would be necessary with each generation to keep within the limits of variation admitted by McDougall, such explanations cannot be regarded as satisfactory.

Other criticisms have, in the main, accepted McDougall's technique as sufficiently consistent throughout the experiment, but have endeavoured to explain his results in terms of factors other than that of the inheritance of acquired characteristics. One obvious criticism, advanced by Sonnborn and Agar and examined by Crew, is that McDougall unwittingly selected the brightest animals in his experimental group for breeding. That this is

possible in apparently random selection is known to everyone who has worked with animals for any period. However, Crew was satisfied that in his case there was no such favourable selection and thinks it unlikely, therefore, that there would be in McDougall's experiment, and, furthermore, McDougall specifically controlled for such selection in his group of adversely selected animals. The fact that these animals also gave evidence of increased facility with successive generations makes it relatively unimportant whether or not there was favourable selection in his Tank rats.

Both Agar and Crew have criticized McDougall for failing to maintain adequate control groups in his experiment. Agar points out that over a long period of intensive inbreeding there may be progressive changes in the general constitution of the animals, and that such changes might facilitate the performance of McDougall's task. Since all these experimenters agree that less vigorous animals learn more quickly on this task, this criticism may be valid. McDougall states in answer to it, that he observed no such progressive change, but the only really satisfactory control would be the maintenance of a group from the same original stock, subjected to the same laboratory conditions, and inbred in a similar manner.

Crew criticizes McDougall for not having maintained adequate pedigree charts, so that he is unable to say which of his original stock are represented in his later generations. Crew's analysis of his pedigree and record charts led him to postulate the existence of 'quick' and 'slow' rats, 'quickness' being a Mendelian dominant and 'slowness' a recessive. On these grounds, he explains the improvement in the average number of errors per rat in McDougall's experiment as showing merely an increasing number of 'quicks' per generation. As he further states that a 'quick' may make a poor score owing to the action of numerous chance factors, adverse selection may result in a heterogeneous group of 'slows' and 'latent quicks'. If now unconsciously favourable selection is exerted, the 'latent quicks' may be chosen for breeding, and hence a decrease in average errors could be expected. While it may be that rats do differ in some general factor, especially in some such factor as 'photo-phobia', Crew's explanation of the results of McDougall's adversely selected group seems somewhat improbable, particularly as 'latent quicks' keep appearing for fourteen generations.

None of these experimenters seem to have considered the work of Tryon in breeding 'bright' and 'dull' strains as measured by maze performance, or Krechevsky's analysis of these strains. Tryon has bred rats selectively according to their ability on the California automatic maze, and, in

a very carefully controlled experiment, has shown clearly that the offspring of 'bright' parents contain more 'brights' than 'dulls', and the offspring of 'dulls' more 'dulls' than 'brights'. The interesting point here in connexion with Lamarckian inheritance, however, is that both strains, 'dulls' as well as 'brights', became progressively better at learning this maze. Tryon inclines to the belief that increased vigour was responsible for the improved performance, but admits the possibility of Lamarckian inheritance.

Krechevsky has analysed the performance of these strains on various problems, and has concluded that they do not differ in any general factor; that is, 'brights' are not 'brights' on all problems, but rather that the difference is one of specific abilities. 'Brights' are good at maze problems because they utilize 'spatial hypotheses' almost entirely, that is, their reactions are governed by spatial cues, while the 'dulls' use primarily visual hypotheses. This penalizes them on a maze, but might assist them in any brightness discrimination test. On McDougall's test, one would assume that Tryon's 'dulls' would be Crew's 'quicks', because they would be 'photo-phobic' and would react on a basis of the differential illumination of the two paths, while the 'brights' would more readily adopt spatial hypotheses such as position or alternation habits.

The position regarding Lamarckian inheritance of acquired habits, on the basis of these experiments with rats, seems to be as obscure as ever. McDougall and Tryon have obtained evidence of an increased facility on a specific task with successive, trained generations; Crew and Agar, under conditions resembling McDougall's, have obtained no such evidence. The reasons for this discrepancy are not clear from the published accounts. It may well be that faults in the experimental techniques are responsible, and that this particular technique will not give trustworthy results concerning inheritance.

McDougall's task is open to criticism on two lines: (1) that an avoidance habit is not really suitable for an inheritance problem, since avoidance reactions are closely knit with such innate factors as fear, timidity, etc., the inheritance of which may certainly not be Lamarckian; and (2) that it provides a very untrustworthy measure of learning ability. All the experimenters who have used it comment on the large element chance plays in producing behaviour which meets the criterion of learning adopted. Crew, in fact, states that thirty-nine of his animals never received a single shock, and, therefore, obviously cannot have 'learned' the differentiation. Others may satisfy the criterion merely by adopting an alternation habit which happens to coincide with the alternation

of the 'correct' alley. If they get 'out of step' they may then make 100 per cent errors. That such an occurrence is possible betrays a poor experimental technique, and raises serious doubts as to the validity of any results obtained with it. Furthermore, the practice of allowing animals to escape by the 'wrong' alley, differentiating it as an error merely by the presence of shock, is poor from the point of view of speed of learning, and trustworthiness of results. Apart from the chance factor as to when and how often the animal encounters both conditions of escape-shock and escape-no-shock, a violent shock can produce marked neurotic symptoms, which may result in purely random activity, or may, in some cases, result in a stereotyping of the error. Crew, in fact, gives a vivid description of violent, emotional and purely random activity lasting for as long as a hundred trials resulting merely from one violent shock.

Without enumerating more of such experimental artefacts here, it is obvious that trustworthy

comparisons between successive generations would be a very hazardous task where chance factors can have so marked an effect on the rate of learning. Future research would do well to use a more trustworthy task, and to control not only the constitutional factors so rightly emphasized by Crew and Agar, but also that type of factor shown by Kroechevsky to be responsible for the differentiation between Tryon's strains. G. C. DREW.

Obituary Notices

Dr. Calvin B. Bridges

THE untimely death of Dr. Calvin B. Bridges, of the California Institute of Technology, on December 27, a fortnight before the fiftieth anniversary of his birthday, will be deeply mourned by the many who appreciated his work and his personality.

One of the foremost in the iconoclastic work of creating the modern science of genetics, in the place of what passed as the 'classical' points of view in that field, Bridges was notable also as one who approached the wider problems of life in a spirit as rationalistic and as unfettered by traditional dogmas as that in which he dealt with his own speciality, and although he held no teaching positions, his influence in the suffusion of this attitude was considerable.

Bridges was brought up in a small town in the wilds of Northern Lake Champlain, in a family of very moderate means, of pre-revolutionary American stock (including even an American Indian strain). At Columbia College he naturally gravitated into scientific lines and, although he was hampered by the need of earning money while studying, both for the support of himself and, very soon, of a family, his initiative and ability won him in 1910, while yet an undergraduate, a position as personal assistant to Prof. T. H. Morgan in the work which the latter was just beginning on *Drosophila melanogaster*. Bridges' chief task here was to look for and test mutations, and practically his entire career has been an expansion of this work, in which he quickly became the leader. Almost immediately the work proved to be the beginning of a new trail. It became

Bridges' passion to follow out this new trail logically everywhere it led, and to work and rework it until it became a broad highroad with many branches, opening up hitherto unsuspected territories. Often the results thus arrived at were in conflict with older beliefs, based on less exact evidence, and in ruthlessly brushing aside the latter he naturally aroused the opposition of those who could not abandon the older modes of thought.

Bridges carried out the same kind of process in regard to the more general problems of the time and in his own personal living, thereby suffering considerable misunderstanding and antagonism on the part of others, which hampered him in the pursuit of his profession. But he always remained true to his own concepts and ideals and did not dissimulate. His open designation of himself as "atheist" in "Who's Who in America" and his opposition to the invasion of the Soviet Union by the Allies shortly after the Great War illustrate his uncompromisingness where his theoretical convictions were concerned, and his lack of faith in prevailing doctrines and institutions. In place of the latter, however, he substituted an ardent belief in the success of future human co-operation, in matters social and economic, and in the radical application of physical and biological science, including genetics, to human affairs.

Through the remarkably energetic and methodical character of his scientific work, including such an apparently trivial but effectively revolutionary change as the introduction of the binocular microscope for the examination of *Drosophila* material, he succeeded in

finding considerably more spontaneous mutations than all other *Drosophila* workers together. He made it his duty to determine the place, in the genetic scheme, of all the changes which he found, and continually to refine upon the conceptual system which they constituted and which, as his work helped to prove, represented the actual material plan of the germ plasma. It was in the course of this systematic testing that he happened, one after another, upon that series of unusual cases which proved to be, not mutations in individual genes, like the rest, but abnormalities of whole chromosomes, of chromosome parts, and of entire sets of chromosomes, and which served as the starting point of most of our modern knowledge of 'chromosome mutations'.

The first of these great contributions of Bridges to genetics was his discovery of non-disjunction, first of the sex chromosomes (1913, 1916) and later of the fourth (1921), together with his working out of its mechanism and of its cytology. It was the striking visual demonstration of the chromosome theory of heredity thus provided which first convinced Bateson, and along with him many other sceptics, of the truth of this theory as a whole. But at least equally important, in its actual pushing forward of our genetic knowledge (as distinguished from the confirmation of things for which cogent evidence really existed already), was his discovery and working out of cases of deficiency (1915, published 1917, *et seq.*) of a part of a chromosome, and of the first translocation (1918, published 1919, *et seq.*). His discovery of triploids (1921), with its proof of the then disputed idea that sex determination depends upon the relative doses of interacting genes, opened up new chapters in our understanding not only of sex determination but also of the manner in which genes in general exert their effects. While in the interpretation and in the planning of the attack on all these cases he enlisted the forces of the whole group of *Drosophila* workers, his initial discovery of the cases, his recognition of the fact that their peculiarities were such as to make them worthy of special studies, and his exemplary prosecution and presentation of these studies themselves, were direct results of that combination of assiduity and intelligence, of method, of painstaking attention to detail, and of following up all clues to their logical conclusions, which always characterized Bridges' manner of working.

In recent years, applying this same meticulousness to the cytological investigation of the giant (multiple) chromosomes of the salivary glands, the possibilities of which had been revealed by Painter (1933 *et seq.*), Bridges, working with renewed vitality on this new branch of the old trail, succeeded in developing amazingly upon the technique and the exactitude of the results; he invented (independently of Koltzoff) the 'polytene' explanation of these chromosomes, and made the important discovery that the remains of 'duplications' produced in past evolution by a process of chromosome breakage and reattachment of parts, similar to that occurring in observed translocations, could still be detected by direct observation in the chromosomes normal to the species. This, and the gathering together and systematization of the multi-

tudinous extant material on *Drosophila* mutations and technique, in the 'Drosophila Information Service', constituted the invaluable work upon which he was still engaged at the time of his death.

Bridges suffered more than most men of science from the hardships attendant upon the following out of new trails of thought and action both in his scientific work and in general. But, though in a sense single-minded, he preserved his early freshness of attitude, boyish enthusiasm, sunniness of character and friendliness. He did not let scientific rivalry interfere with his personal friendships, and threw himself into them whole-heartedly and without suspicion. Combined with calculation, he preserved a charming naiveté. He was most patient and kind in helping less advanced workers. He was engrossed in his work to a point of absent-mindedness which became a byword to others. His personality was such that it is likely to pass into legend. But his work will undoubtedly form a solid indestructible part of the basic structure of all future biological science.

H. J. MULLER.

Mr. M. A. Phillips

MR. MONTAGU AUSTIN PHILLIPS, the well-known lecturer on natural history subjects, died on January 11, aged fifty-nine years. He had been for many years associated with the British Museum (Natural History) where he acted as a deputy guide-lecturer. Originally he assisted the late Mr. J. H. Leonard, the first official guide-lecturer to be appointed at the Museum, and after Mr. Leonard's death in 1931 he carried on the whole of the guide work until the appointment of the second official guide-lecturer, Miss Mona Edwards, in October 1932. From that time onwards, Mr. Phillips acted as an auxiliary lecturer at the Museum, and was so engaged up to the close of last year, when ill-health caused him to abandon his work. In addition to lecturing in the Museum he had for many years been a well-known lecturer at schools, societies and field-clubs and travelled extensively in connexion with this work. In his lectures, Mr. Phillips had a certain charm of manner which made even the dullest of subjects attractive to his audience, whether it was a large audience at a 'sit-down' lecture or a small group of people in the Museum Galleries.

Mr. Phillips was educated at King's College, London, and was a fellow of most of the senior scientific societies, including the Linnean, Zoological, Geological, Geographical and Royal Entomological Societies; he was in addition a member of the British Ornithologists' Union and was associated also with the Royal College of Organists, being an enthusiastic musician.

GUY DOLLMAN.

Dr. C. J. Gahan, keeper of the Department of Entomology in the British Museum (Natural History) during 1913-27, on January 21, aged seventy-seven years.

Prof. A. Sauveur, professor of metallurgy in Harvard University during 1906-35, aged seventy-six years.

News and Views

Co-operation Between the Nations

ON Friday, January 27, there was broadcast in the news bulletin in German sent out by the B.B.C., and again in the news bulletin in English later in the evening, an appeal, signed by eighteen leading men in science, literature, the arts, and medicine in Great Britain, to "men of good will who value the fruits of civilization" to join together to prevent the catastrophe of war. "A spirit of uneasiness broods over the world", the appeal began, and the peoples everywhere, while they know that warfare between modern States can bring no final good, see the armaments of the nations ever growing. It is time for men to break down the artificial barriers of hatred by which they are in danger of being divided, and "to speak across the frontiers to those who feel as they do". The appeal concluded: "We appeal above all to leaders and people in the great German Reich to use those great gifts by which they have for centuries enriched our common heritage in all fields of human knowledge and activity and to join with us in a supreme effort to lay the spectre of war and enmity between nations, and in a spirit of free and willing co-operation, by which alone can their needs and ours be satisfied, to build with us a better future so that we may not only preserve civilization but hand it down to our children enhanced by our experience".

THE signatories of this dignified appeal were: Lord Willingdon, Lord Derby, Lord Dawson of Penn, Lord Horder, Lord Macmillan, Lord Stamp, Mr. Montagu Norman, the Right Hon. H. A. L. Fisher, Prof. G. M. Trevelyan, Lord Eustace Percy, Sir Michael Sadler, Dr. Vaughan Williams, Sir William Bragg, Sir Arthur Eddington, Sir Edwin Cutyens, Sir Kenneth Clark, Mr. John Massfield, and Lord Burghley. While the real effect of the appeal, through the medium of the broadcast word, will never be assessed, it cannot be doubted that it will contribute to the promotion of that international good will which all right-thinking men must desire.

National Service in Great Britain

THE guide to National Service which has now been issued briefly describes the various civilian services, such as air raid precautions, police, fire services, nursing and first aid, for which volunteers are required, and indicates those for which part-time training in peace time is or is not required. Details are also given of the various branches of the armed forces for which recruits are required and how to join. A Central Bureau is being established by the Ministry of Labour for men and women with professional, scientific and technical qualifications who would be prepared to undertake specialised work in

the event of an emergency. The provisional Schedule of Reserved Occupations includes such classes of scientific workers as bacteriologists (25), chemists (21), engineers (25), physicists (25), from the age indicated, and in his introduction to the guide, Sir John Anderson expresses the hope that workers in such reserved occupations will fit themselves for part-time duties such as air raid precautions at their places of work. The guide and the schedule make it clear that the Government is fully alive to the importance of having available a record of men and women with scientific and technical knowledge. It is to be hoped that, should an emergency arise, the Government will see to it that proper use is made of their services.

The late Mr. S. H. Ray

THE remarkable record of the late Sidney H. Ray as a student of the languages of the Pacific, which Dr. A. C. Haddon reviews in his obituary notice (see *NATURE* of January 28, p. 149) is an outstanding achievement of scholarship in adverse circumstances, which has few, if any, parallels in either field investigation or academic study. Not only was Ray compelled to make the work for which he was peculiarly fitted by genius and temperament the secondary consideration of his scanty leisure, but also he laboured in an unmapped field, in which the difficulties would have taxed the energies and powers of concentration even of a student freed from all other preoccupations. The tragedy of Ray's career, however, lay not so much in the conditions in which his studies were pursued, as in the fact, as he himself would have been the first to contend, that through lack of more adequate leisure so much of the unique linguistic knowledge he had acquired, and still more his reasoned conclusions and inferences from that knowledge, have been lost to science and the world. Many years ago, both the Bible Society and Ray's employers, the London County Council, expressed amazed admiration at his vast erudition, but even though the former was afterwards able to make use of his assistance, both bodies expressed regret that they could not offer him the opportunity needed for the development of his powers. When a unique capacity for the advancement of knowledge such as that possessed by S. H. Ray is brought to light, it is surely the duty of the community to see to it that it is not wasted, as undoubtedly it was to a great degree in this instance.

Petrus Camper (1722-1789)

THE Faculty of Medicine of the University of Groningen, in collaboration with the *Netherlands Journal of Medicine* and the Netherlands Society for the History of Mathematical and Natural Sciences,

will commemorate in April next the one hundred and fiftieth anniversary of the death of Petrus Camper, physician, anatomist, obstetrician and artist. The name of Camper is perhaps now most frequently recalled in connexion with his contributions to the foundation of craniology as a scientific study. He was the first to make use of the facial angle—an invention apparently of the artist Dürer—as a factor in racial discrimination. The occasion is not without special interest to science in Great Britain, as it was during Camper's visit to London in 1748, through his association with Pringle, Mead and Pitscottie, and his familiarity with the collections of Sir Hans Sloane, Collinson and others that his interest in natural history was stimulated, if not actually aroused. Camper was born on May 11, 1722, at Leyden, where he was educated and took his degree in philosophy and medicine in 1746. He afterwards held professorial chairs at Franeker (1750), Amsterdam (1755) and Groningen (1768), being appointed councillor of State in 1787, two years before his death in 1789. He was among the most distinguished men of science of international standing of his day. Not only was he a fellow of the Royal Society of London, but also he shared with Boerhaave the then unique honour for a foreigner of membership of the Paris Academy of Sciences. His works, of which a collected edition was published in Paris in 1803, covered a wide field, ranging from the physical education of children to detailed studies in anatomy, physiology and natural history. Among his anthropological treatises were studies of the origin and colour of negroes, and on the variation of the facial angle in different races.

Preservation of Wildfowl

An amendment put forward by the promoters of the Wild Birds (Duck and Geese) Protection Bill has secured the withdrawal of the opposition, on behalf of shore-shooters, which has been holding up the Bill in the House of Commons, and it is to be hoped that it will now have a successful and rapid passage. The amendment provides separate close-times for wild duck and geese above and below high-tide mark; further, the date of the period of prohibition of import of wildfowl will commence on February 1. This last is an extremely important feature of the Bill, for it stops the demand for duck caught in decoys on the Continent during the breeding season. The Bill, which is promoted by the International Committee for Bird Preservation (British Section) and has the full support of the Government, is part of a big international scheme to preserve the stock of wildfowl in Europe. The accumulation of adverse effects of modern civilization is having a most serious effect on wild duck and geese. Cold storage, facilities of transport, draining of land, development of arctic areas and over-commercialization by means of decoys are but a few of the factors which are depriving wildfowl of their nesting and resting grounds and causing their destruction on a vast scale. The shooting season is also admittedly too long in many countries. Sweden has already taken drastic steps by prohibiting all shooting in several

of its largest provinces, Denmark and Germany have greatly restricted their shooting seasons and other European countries are alive to the necessity of action to safeguard the general stock of wildfowl before it is too late. The state of affairs in America, where wildfowl have been reduced to a perilously low number, is only too gloomy an example.

Engineering and Social Science

In a recent address to the Manchester and District Association of the Institution of Civil Engineers on the work of the civil engineer in relation to social and international problems, Mr. R. D. Brown urged that engineers are no better qualified for statesmanship or politics than the medical man, the lawyer, the psychologist, the physicist or the parson. Engineering science has nothing to do with solving the social economic and political problems of mankind, and the scientific and the political minds and methods of working have nothing in common. While engineers should be mindful of their duties as citizens, they can only engage in politics if they are prepared to give up engineering altogether and devote their time and energy to a new way of life. Mr. Brown is sceptical of the value of the proposed Council of Engineers, and recommends rather that any man of science, whether an engineer or not, who desires to help in this matter to get into touch with the committee of the newly formed Division for the Study of the Social and International Relations of Science of the British Association. The committee will require all the help it can obtain, whether from engineers, chemists, biologists, publicity experts or others. Mr. Brown referred to the importance of thinking about such problems of divesting the mind of all prejudice, superstition and humbug, and of laying aside all preconceived political, social or racial notions. He considered the committee's work might prove to be the most important investigation ever undertaken by the British Association.

Steel Manufacture in South Wales

THE project of a new steel works and rolling mill at Ebbw Vale in Monmouthshire designed on the latest lines and including a hot strip rolling mill for continuous production has aroused considerable interest. The size of the undertaking may be estimated from the fact that the plant cost about ten million pounds, and is designed to give an output of 600,000 tons per annum of tin plate and sheet steel of the highest quality. The raw materials, coal and lime stone, are in the immediate vicinity and transport facilities are good. The electrical part of the equipment is very complete. The works have an installed capacity of 250,000 kw. and will consume approximately 200 million units per annum. The Victorian generating station of the former Ebbw Vale Company has been largely reconstructed, but to provide the greatly increased demand of the new plant a grid supply at 132 kv. is brought from the Upper Boonville power station, a distance of eighteen miles. The supply of iron ore for the works is obtained from Northamptonshire, and ample coal is obtainable

from the neighbouring collieries. The coke oven plant is designed to deal with 1,370 tons of coal a day, a complete by-product recovery plant being provided. The two blast furnaces have been entirely reconstructed, the output of each being increased to 3,500 tons of pig iron. The molten iron from the blast furnaces is taken direct to the steel works, but any surplus not required at the moment is diverted to a pig-casting shop. The molten metal is first poured into a 1,400-ton mixer, where it is kept in a molten state until it is required to charge the furnaces. The molten steel is discharged from the furnaces at floor level and is cast into ten-ton ingots.

River Control in Great Britain

A BROADCASTER issued by Political and Economic Planning (PEP) deals with the difficulties which regionalism presents to the efficient operation of specialized and technical services, as exemplified in the control of rivers. Already the Ministry of Health, the Ministry of Agriculture and Fisheries, the Ministry of Transport, the Electricity Commissioners, the Board of Trade, the Mines Department, the Home Office and the Development Commissioners are concerned with different aspects of water supply and the control of rivers in Great Britain. The Land Drainage Act of 1930 was a consolidating and amending measure based on the recommendations of a Royal Commission and created some forty-nine catchment areas which cover the greater part of England and Wales, but the process of constituting and reorganizing drainage boards within catchment areas is not yet complete. Navigable rivers are controlled mainly by 51 public bodies, and waterways are owned by the railways and 31 other companies.

In the even more important matter of water supply, there are at present 782 local authorities and 50 joint authorities supplying, besides 236 companies and 1,053 private proprietors. To secure further rationalization and conservation of water supplies, nine regional advisory committees have been created, and a sub-committee of the Advisory Water Committee recently recommended that other committees should be created in the Greater Metropolitan Area, South Wales and the North-East. The possibility of damage to mains and reservoirs during air raids makes working agreements even more essential. The control of sewage presents yet another problem calling for co-ordination, while there are nearly fifty fishery boards concerned to prevent pollution of rivers, which may come into conflict with the navigation authorities. Moreover, town and country planning schemes are required to prevent ribbon development along river banks and undue pressure to develop sites. It is suggested that the Thames Conservancy Board, which is both a conservancy and catchment authority and has power over pollution and fisheries, is a model of what is required. How far it would be possible to entrust the general supervision of all water interests to one central department is a matter for discussion.

British Museum (Natural History): Recent Acquisitions

THE Trustees have purchased for the Department of Mineralogy uncut crystals of topaz, sapphire, and a set of seven rough crystals of ruby from Mogok, while cut stones are represented by a good example of deep lilac-coloured kunzite and a remarkable clear yellow cassiterite, cut from a stone from Uganda. A small diamond of considerable interest in the history of diamond-mining has been presented by Sir Ernest Oppenheimer. It is the first diamond taken from the first of the Kimberley diamond mines—the Jagersfontein—and was found by William Wreford Paddon. Dr. Stanley Smith, University of Bristol, has presented a specimen of natural coke showing columnar structure, from a quarry near Cockfield, County Durham. The coke was formed where a coal seam had been burnt out by a basalt dyke. Miss Beatrice O. Corfe has presented to the Department of Botany more than three hundred paintings of British flowers. The Department already possesses a number of Miss Corfe's paintings which were purchased some years ago. The paintings are artistic and at the same time botanically sound, and a number of them suitably adapted have been reproduced in the Museum series of botanical picture postcards. As a result of a short expedition to St. Lucia undertaken for the Museum by Mr. Harold E. Box, more than three hundred flowering plants and ferns were obtained chiefly from the higher altitudes of the mountains in the interior of the island. Unfortunately, Mr. Box's visit coincided with the almost unprecedented rainfall of November last, and twenty out of twenty-eight days had to be spent in camp or indoors.

Fisheries Research in Hong Kong

At the recent meeting of the British Association in Cambridge, the president of Section D (Zoology), in a highly important address, directed attention to the fact that the British Empire as a whole is regrettably deficient in fisheries research and administration. This is especially true of British territories in the Far East. In consequence, highly skilled and intensely industrious Japanese fishermen have in recent years been exploiting practically all the great fishing grounds of the Pacific region and landing large quantities of fish at most of the principal fish-markets—both British and foreign—along the coasts of China, India, Philippines, Malaya and Dutch East Indies. It is highly gratifying, therefore, to note that the University of Hong Kong recently has published a small handbook (*"Common Marine Food Fishes at Hong Kong"*). By G. A. C. Harklote and S. Y. Lin. Pp. 75. Hong Kong: G. A. C. Harklote, The University. n.d. n.p.) written in both English and Chinese, describing forty of the commonest food fishes landed at Hong Kong fish-markets. Each fish has been given its scientific name, Chinese name or names, and an English name—in some instances specially coined for this book. This is followed by a brief but useful description accompanied by a black-and-white illustration, with notes on distribution, seasonal abundance, price and food value. At the end of the book are set out twelve Chinese and seventeen European recipes for the cooking of fish dishes.

As a preliminary contribution to our knowledge of the food fishes of Hong Kong this book is most valuable. It is greatly to be hoped, however, that it merely heralds the inauguration of a much more far-reaching and systematic study of the marine resources of the Hong Kong region, to be undertaken by or under the auspices of the University; or, better still, by a specially built and properly equipped fisheries research laboratory.

The Lighting of the Western World Fair

THE illumination of the San Francisco Panama-Pacific Exposition of 1915 set a high standard in exhibition lighting which was for long unsurpassed. According to an article on the Golden Gate Exposition, which appeared in the *Electrician* of January 20, it will be far surpassed by this new exhibition on Treasure Island in San Francisco Bay which will be opened on February 15. The gem-like appearance of the various buildings is mainly due to the use of an inexpensive insulating material called 'vermiculite'—an alteration of mica expanded by electric heat to fifteen to twenty times its original size. Applied to wet stucco, vermiculite imports an antique finish which scintillates with light. The sea wall and roadway lighting of Treasure Island is designed to be in keeping with the main project, and it is considered that it will establish a new milestone in the history of illumination. Projectors concealed in troughs floodlight the walls in white. Cylindrical golden amber lanterns are spaced on approximately sixty-foot centres along the entire facade for roadway illumination and to break up the flatness of the long lighted wall. Spectacular lighting has been arranged for the Courts of Pacifica and of the Seven Seas. The sculptured relief work consisting of submarine scenes is painted with paints that fluoresce under the ultra-violet light provided by concealed projectors from below. Nearly three hundred ultra-violet mercury floodlights, each of 100 watts capacity, are being used for fluorescence effects on outdoor murals. More than two hundred underwater floodlights are being installed, and altogether the outdoor lighting equipment comprises more than 10,000 units. The interiors of exhibition buildings are uniformly lighted by day and night; they have no windows. At the high points of the main buildings a concentrated type of reflector is employed while at lower points reflectors with layer spread are used. The total illumination of the 400 acre exposition site is estimated to require 40 million kilowatt hours during the 288 days the fair will be open.

Standard Television Terms

Now that television broadcasting has become a public service in Great Britain, it is very desirable that, so far as possible, standardised terms and definitions should be used in connexion with the technique of this subject. The British Standards Institution has already made some progress in the matter in so far as the "Glossary of Terms used in Electrical Engineering" (No. 205-1936) contains two sub-sections dealing with terms used in connexion with television and with cathode ray tubes re-

spectively. More recently, the Radio Manufacturers' Association has given consideration to the desirability of television equipment manufacturers and television engineers using a common form of nomenclature. It has been decided that, so far as possible, the technical terms given in the above Glossary should be used by manufacturers in their literature and in any instruction classes which they may operate. In addition, the Association has compiled a list of titles which are recommended for use in working the controls of television receivers. Fourteen titles are listed and described, and in so far as the modern receiver may have upwards of six hand controls directly accessible to the user, this would seem to be a very sound recommendation. It is understood that the R.M.A. has communicated the above recommendations to technical institutes providing radio engineering courses, with the view of securing their co-operation towards the desired objective.

Marine Engineering Collection

H.M. STATIONERY OFFICE has recently published a new descriptive catalogue (price 2s. 6d. net) of the Marine Engineering Collection in the Science Museum. Nowhere else is to be seen anything like so large and representative a collection of marine engineering models, drawings, photographs, etc., as that at the Science Museum; and a close study of this catalogue and the companion volume on history and development, will repay anyone with an interest in the subject. Nearly 400 exhibits are described clearly and accurately, and there are 15 plates. Among the illustrations are photographs of the engine built by David Napier in 1811 for Henry Bell's *Comet* and of one set of the main steam turbines of the *Queen Mary*. Both these vessels were built and engined on the Clyde, but some of the most beautiful models in the collection are those of engines built on the banks of the Thames when the names of Penn, Seaward, Maudslay and Field were as widely known as those of the marine engineers of the Clyde and the Tyne are to-day. In connexion with this it is perhaps permissible again to recall the debt of marine engineers to Bennett Woodcroft, who by securing the early engine built by Symington, and that of the *Comet*, laid the foundation of the fine series of exhibits described in this catalogue of marine engines.

First-Aid Services and Air Raid Precautions

FOLLOWING the recent transfer from the Home Office to the Ministry of Health of responsibility for approving the air raid precautions schemes of local authorities in respect of first-aid posts and ambulance services, the Minister of Health has forwarded to all local authorities responsible for such schemes and to every voluntary hospital an explanatory communication (Circular 1764. H.M. Stationery Office. 1d. net). There should be at least one medical man, and if possible a trained nurse, in addition to the volunteer personnel, in attendance at every aid post. An aid post should be attached, or be very close, to all hospitals which are to be used for the initial reception of casualties, and some of the smaller hospitals,

clinics, health centres, etc., might be transformed into aid posts. In some areas, it is suggested, the fixed posts should be supplemented by mobile units, which could give medical aid on the spot. Ambulances that may be required, the organization of ambulance services, and their personnel, are described, as well as the use and training of women for ambulance driving. Finally, the Minister urges all responsible authorities to press on with their schemes and proposals without delay, and desires that an interim report be furnished by every authority involved.

The Placing of Children in Families

THE Advisory Committee of the League of Nations has issued a report upon this subject ("The Placing of Children in Families". Geneva, 1938. Vol. 1, price 3s.; Vol. 2, price 5s. Messrs. Allen and Unwin, 40 Museum Street, W.C.1). To begin with, the Child Welfare Committee of the League planned a survey on the placing of children in families as part of its general inquiry into the treatment of neglected and delinquent minors, but it was afterwards decided to treat independently the whole problem of placing in families as a method of child care. The first volume of this report presents the principles accepted as underlying provisions for child care, the characteristic features of the different systems employed in various countries, and the organization of social services to direct 'placing'. Vol. 2 describes the various systems of placing children in families that are now employed in different parts of the world.

Buildings for the Academy of Sciences of the U.S.S.R.

A LARGE plaster-of-Paris model of the main new buildings of the Academy of Sciences of the U.S.S.R. is now on view at the Academy's premises in Bolshaya Kuluzhakaya Ulitsa in Moscow. The buildings were designed by A. V. Shohusev. The site for the buildings most favoured is on the Frunze Embankment of the Moscow River. The new buildings of the Academy, according to the plans, consist of five blocks with a volume of 880,000 cubic metres. In the centre of the architectural ensemble is the main block for the presidium of the Academy. The hall is large enough to seat 2,000 persons. There are also four smaller auditoriums. Near the main hall are rooms for the demonstration of films and for broadcasting; also a post and telegraphic office and an information bureau. A block has been set aside for the library and storage premises for fifteen million volumes. On either side of the block for the presidium are buildings to accommodate two museums, one of which will be the Natural History Museum.

The Food and Drugs Act, 1938

THE Minister of Health has issued a circular to local authorities and public analysts on the new Food and Drugs Act passed last July, which comes into force next October (Circular 1755. H.M. Stationery Office. 2d. net). This Act represents a great simplification of existing food and drugs law, some of which dates back to the sixteenth century, and opportunity has been taken to introduce, into the general law, provisions which have up to now been included only in Local Acts. Among new provisions

which will become enforceable are the registration by local authorities of premises used for the sale or manufacture of ice cream and the preparation or manufacture of sausages or preserved food. Ice cream vendors must have their names and addresses on stalls, carts and barrows, and this requirement may be extended to all or any foods by the local authority. Slaughterhouses and knacker's yards will all in future be licensed for limited periods only, and new requirements are laid down as regards rooms, yards, etc., in which food is sold or prepared for sale.

Earth Tremor in the Lipari Islands

A STRONG earth tremor with epicentre near latitude $38^{\circ} 40' N.$, longitude $15^{\circ} 7' E.$ occurred during the night of January 27 and lasted several seconds according to human experience. The shock damaged several buildings, but no casualties are reported. The depth of focus is uncertain, but is unlikely to have been at the surface, as the shock was experienced and caused some apprehension in Messina. Messina has been troubled by earthquakes on several previous occasions, including February 25, 1509, June 8, 1599, March 28 and April 9, 1780, February 5–March 28, 1783 (six altogether), December 28, 1908, September 8, 1905, and October 23, 1907. The one on December 28, 1908, at 5 h. 21 m. was probably the most severe, nearly destroying Messina and Reggio, and causing the deaths of 77,283 people. On that occasion there were two epicentres in the Straits of Messina, the northerly one being the most important. The shock lasted 30 sec., caused sea-waves 38 ft. high at San Alessio, and subsidences of 22.9 in. two miles south of Reggio and 28 in. within two miles of Messina harbour.

The Chilean Earthquake

CHILE is one of the great seismically active regions in the world and part of the circum-Pacific ring of instability. During the night of January 24, an earthquake which lasted according to human experience for three minutes, shook an area greater than 40,000 square miles embracing Talca and Concepcion, and caused the deaths of approximately 15,000 people. It was the most severe for twelve years in Chile and the most destructive of human life since Quetta (India) in 1935. The three towns of Chillan, Pailalque and Parral are reported completely destroyed; Concepcion, Talcahuano, San Rosendo and Los Angeles are severely damaged, and Talca, Angol, Lota and Curico damaged. At Talca the prison collapsed, fires broke out at the port of Talcahuano, the cathedral tower at Vaparaíso swayed dangerously, and half Concepcion is reported in ruins. From the available macroseismic evidence the epicentre appears to be near lat. $37^{\circ} S.$ and somewhat to the east of long. $73^{\circ} W.$ The shock appears to have had a normal focal depth and to have caused some surface faulting, and the railway line is reported damaged in several places, including one point about 12 miles south of Talca. Two trains are reported derailed.

CONCEPCION has had an unfortunate history seismically, having been severely damaged on no fewer than six occasions: February 9, 1570, March 15, 1657, July 8, 1730, March 25, 1751, February 20,

1835, and July 23, 1898. The last was the least severe, but the five others were all accompanied by sea waves. On February 20, 1835, Concepcion was utterly ruined. The sea waves were 28 ft. and more in height, causing damage even as far north as Fernandez (420 miles). On this occasion the coast was raised by 4-5 ft., though it afterwards subsided by half that amount. The epicentre on the present occasion is probably farther inland than on former occasions, as most damage appears to have been done to the east of Concepcion and no sea waves are mentioned. The most active epicentre for moderate shocks recently appears to have been lat. $38^{\circ}0'$ S., long. $73^{\circ}5'$ W., which is a little to the south-west of the one suggested in the present instance, though more precise information concerning this latter must await the records of seismograms at observatories throughout the world.

Announcements

PROF. ARTHUR CONWAY, professor of mathematical physics in University College, Dublin, has been appointed by the Pope a member of the Pontifical Academy of Sciences to occupy the seat left vacant by the late Lord Rutherford.

PROF. P. G. H. BOSWELL, who has just retired from the chair of geology in the Imperial College of Science and Technology, has been appointed emeritus professor of the College.

THE annual award of the Pittsburgh Section of the American Chemical Society has been made to Dr. George H. Clapp. The award, an aluminium plaque suitably inscribed, is made in recognition of outstanding service to chemistry in the Pittsburgh district. Dr. Clapp, who recently celebrated his eightieth birthday, directed, with Captain Hunt, the firm of Hunt and Clapp, which afterwards acquired the Pittsburgh Testing Laboratory. With Captain Hunt, Dr. Clapp was instrumental in bringing to Pittsburgh Charles M. Hall and in organizing the Pittsburgh Reduction Co., which is now the Aluminium Co. of America. Dr. Clapp's hobby is conchology.

SIR FRANK SMITH, who has just retired from the post of secretary of the Department of Scientific and Industrial Research (NATURE, Jan. 14, p. 56), has taken up an appointment with the Anglo-Iranian Oil Co., Ltd., to advise on the company's research and development work.

AN appeal will be broadcast from all national stations of the B.B.C. at 8.45 p.m. on Sunday, February 5, on behalf of UFAW (Universities Federation for Animal Welfare). This body differs from many having kindred objects in that its membership is drawn from the universities and includes a number of distinguished men of science, particularly biologists. The appeal will take the form of a dialogue between "Fougasse", the art editor of *Punch*, and the Hon. Harold Nicolson, M.P.

THE sixth International Congress of the Technique and Chemistry of Agricultural Industries will be held in Budapest on July 10-20.

ELECTION to Beit Fellowships for scientific research will take place on or about July 7. Not more than

three fellowships will be awarded. Applications must be received on or before April 6. Forms of applications and further information can be obtained from the Rector, Imperial College, South Kensington, London, S.W.

A SCANDINAVIAN Summer School in Norway and Sweden is being arranged by the Association for Education in Citizenship, to be held during August 5-22. The party will stay in colleges at Bommersvik, near Stockholm, and at Syverud, near Oslo. Lectures in English on the political, economic and educational developments taking place in their respective countries will be given by Norwegian and Swedish experts. Further information can be obtained from the secretary at the Association's offices, 10 Victoria Street, S.W.1.

THE annual joint meeting of the Institute of Radio Engineers and the International Scientific Radio Union (American Section) will be held in Washington, D.C., on April 28-29. Meetings of other scientific societies will be held in Washington during the same week including the National Academy of Sciences, American Physical Society and American Geophysical Union. Papers on the more fundamental and scientific aspects of radio will be presented. The programme will be published in the April issue of the *Proceedings of the Institute of Radio Engineers*. Further information can be obtained from S. S. Kirby, National Bureau of Standards, Washington, D.C.

THE annual malaria control course for laymen will be held at the London School of Hygiene and Tropical Medicine commencing on June 26. The course will be under the direction of Sir Malcolm Watson and the staff of the Ross Institute of Tropical Hygiene. The course lasts five days. It includes instruction on mosquitoes and their habits, drainage and other measures for the prevention of malaria. It is illustrated by lantern slides, films, demonstrations of the living insect in the various stages of its history, and a practical demonstration on Hampstead Heath. Application to attend the course, which is free, should be sent in as early as possible to the Organizing Secretary, Ross Institute of Tropical Hygiene, Keppel Street, Gower Street, London, W.C.1.

THE thirty-first annual general meeting of the Institute of Metals will be held in London on March 8-9. In addition to the usual list of papers to be read and discussed on the first day of the meeting, there will be two general discussions extending over the whole of the second day of the meeting. At the morning session the subject of debate will be "The Effect of Work on the Mechanical Properties of Non-Ferrous Metals", and in the afternoon the discussion topic will be "Industrial Application of Spectrography in the Non-Ferrous Metallurgical Industry". On March 8, the second annual award of the Institute of Metals Medal will be made, the recipient being Sir Harold Carpenter. The medal, which is of platinum, is the gift to the Council of the Institute, which decides its award, of the Mond Nickel Co., Ltd. The first award of the medal was made last year to Sir William Bragg.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 207.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

A New OH Band in a Carboxylic Acid

RECENT investigations of infra-red spectra in the region of 3μ by Davies and Sutherland¹, and Buswell, Rodebush and Roy², have shown that the COOH group of carboxylic acids has an absorption

ABSORPTION OF *o*- AND *p*-METHOXYBENZOIC ACIDS IN CARBON TETRACHLORIDE. CELL LENGTH 1 CM. TEMP. 20°C.

band close to that given by the OH group in alcohols and phenols³ ($\sim 2.8\mu$) as well as a large region of absorption at longer wave-lengths. There is, however, an important distinction between the acids and other compounds. While alcoholic and phenolic bodies are generally unassociated in carbon tetrachloride at concentrations of 0.01 mol./l. and lower (compounds such as salicylic aldehyde are exceptions and are completely associated intramolecularly), the acids are much more strongly associated and intense absorption in the association region is found at concentrations so low as 0.002 mol./l. at ordinary temperatures.

It has not yet been shown whether the acid complexes split up completely at still lower concentrations, although the infra-red investigations of Rodebush *et al.*², and polarization measurements⁴ would indicate its probability. A breaking up of the complexes is fairly easily achieved by working at higher temperatures. The double COOH ring of associated

acids has been well established by electron diffraction measurements of Pauling and Brookway⁵, and offers a ready explanation of a number of physical properties of carboxylic acids. Thus terephthalic acid, diphenyl-4:4'-dicarboxylic acid, and many other dibasic acids have high melting points and are sparingly soluble in most organic solvents. Clearly if the molecules are associated at both COOH groups, the substance will exist in chains of considerable stability and will not easily dissolve or melt. Diphenic acid (2:2'-dicarboxylic acid) is quite soluble, on the other hand, and here the contiguity of the two COOH groups makes association into large complexes unlikely.

In carboxylic acids, the OH band is displaced somewhat from the position found in other hydroxylic bodies (2.75μ in primary alcohols, 2.77μ in phenol, and $\sim 2.83\mu$ in acids) and at ordinary temperatures the band obtained is very small, while the association band is more intense than with the other hydroxylic bodies and extends over a greater wave-length range, about 3.0 to 4.2μ (cf. Rodebush *et al.*²). The simple doublet structure attributed to this band by these workers in our view requires further investigation, and no one, so far as we know, has yet advanced an explanation of the great width and intensity of the band.

In the accompanying figure we give curves for *o*-methoxybenzoic acid at concentrations of 1/50, 1/150 and 1/500 mol./l., and for *p*-methoxybenzoic acid at 1/500 mol./l. (almost the limit of solubility), both in carbon tetrachloride. It will be observed that the *para*-compound gives the usual carboxylic acid curve, with an OH band at 2.824μ and an association band at 3.4μ . The sharp peaks superimposed on the association band are readily identified as being due to OH vibrations of the benzene ring and of the OCH_3 group. The *ortho*-compound, in addition to an OH band at 2.833μ and the usual association band, has a new band of considerable intensity at 2.974μ , totally distinct from those usually found in acids. It is well recognized that *ortho*-compounds exhibit abnormal behaviour in absorption (cf. Wulf *et al.*⁶, and Pauling⁷) and *o*-methoxybenzoic acid is an example of this. The phenomenon seems to indicate the existence in solution of two monomeric forms of *o*-methoxybenzoic acid:

Form (2) will behave like the *p*-acid, while in Form (1) interaction between the oxygen of the methoxy group and the OH of the COOH group will prevent normal association of two COOH groups, and so a strong monomeric OH band should be observed, although with a frequency somewhat slower than that of the unaffected OH. Giving the C—O and O—O bonds the lengths shown in (1) and making the angles indicated all equal to 122° , it is found that the O—O distance is close to 2.7 Å., the value accepted for hydrogen bonding. The hydrogen atom need not be exactly in line with the oxygen atoms as shown, although little strain of the normal COH angle would be required for this to be the case.

It will be noted that the association band is smaller in the *ortho*- than in the *para*-compound at a given concentration, and this supports the idea that the new band has formed at the expense of the association band. As is to be expected on this view, the *ortho*-compound is more soluble in carbon tetrachloride than is the *para*-compound (ratio $\sim 10:1$); the latter also has much the higher melting point. The new band bears a strong resemblance to the bands at $\sim 2.9\mu$ found by Errera and Sack³ for ethyl alcohol and phenol in dioxan, where opportunity exists for a somewhat similar interaction.

The *m*-acid gives an absorption spectrum almost indistinguishable from the *p*-acid.

Interpretation of Beta-Disintegration Data

FERMI's original theory of β -decay¹ made a definite prediction as to the energy distribution of the electrons emitted from a β -active element. It was found² that the experimental distribution curves did not agree in shape with this prediction in the sense that the number of electrons of low energy (relative to the upper limit of the spectrum) was considerably greater in the experimental than in the theoretical curves. A modified theory was then proposed by Konopinski and Uhlenbeck (K.U.)³ which introduced in the distribution curve another factor proportional to the square of the momentum of the emitted neutrino. This theory appeared to agree with the facts.

Further experimental evidence, however, revealed a number of facts which did not fit in well with the modified theory: (1) The shape of the observed energy spectra did not fit the K.U. law near the upper limit, but seemed there to follow the original law of Fermi, although the latter did not fit with any other part of the curve⁴; if one determined the position of the upper limit by extrapolation from the K.U. law, one obtained values that were difficult to reconcile either with the observed spectrum or with the other data on the energy balance⁵. (2) The Sargent curves (decay constant against disintegration energy) seemed to agree better with the Fermi theory⁶. (3) The probability of capturing a *K*-

electron, as compared to that of emitting a positron, was found to be much smaller than the K.U. theory would predict, but in reasonable agreement with the Fermi theory⁷. (4) An attempt to develop the K.U. theory into a mathematically consistent scheme showed that it was, at any rate, far more complicated than that of Fermi, and no proof has as yet been given that it can be consistently carried further than to the first order of approximation⁸.

We therefore investigated the view that the original theory of Fermi correctly represents the elementary law; but that the observed spectra, in so far as they belong to 'allowed' transitions, do not represent the effect of a single nuclear transformation, but rather a superposition of different spectra belonging to transitions to different levels of the final nucleus. It is then clear that the resulting energy distribution will contain rather more electrons of low energies, compared to the upper limit of the spectrum, than a single Fermi curve. If the nucleus is left in an excited state, it must eventually lose its energy by radiation, and the crucial test for the suggested point of view is the presence of γ -rays of suitable energy and intensity from all those radioactive bodies which have 'allowed' transitions and the energy spectra of which are known to be different from the simple Fermi curve. The γ -rays might in some cases be absent because the excited state of the nucleus might be a metastable isomer; but this could not be true for all such elements. The restriction to allowed transitions is necessary because in 'forbidden' transitions the shape, even of a single curve, is affected by more complicated factors⁹.

Interpreting from this point of view the electron spectra of ^{10}B , ^{10}F , ^{17}F , ^{12}N , ^{16}O , as given by Fowler, Delsasso and Lauritsen¹⁰, we have estimated the energy and intensity of the γ -radiation to be expected. The results are given in the following table.

Active element	Product nucleus	Energy of γ -ray in Mv.	Number of γ -quanta per disintegration
^{10}B	^{10}Be	5	0.5
^{10}F	^{10}Ne	2	0.7
^{12}N	^{12}C	0.27	0.8
^{16}O	^{16}N	0.5	0.4
^{17}F	^{17}O	0.9	0.6

No great accuracy is claimed for these results since the curve-fitting is very sensitive to the high-energy ends of the electron spectra, which are not very accurately known, and also because we have assumed that only one excited level is involved, whereas there might be more.

The presence of a γ -ray accompanying the disintegration of ^{12}N was indeed reported by Richardson¹¹, who gave its energy as 0.3 Mv. A γ -radiation from ^{17}F was reported by Burcham and Smith¹², and measurements of the energy of this radiation, which are being made by Bower¹³, indicate a value of about 2.2 Mv. Although γ -radiations of the predicted energies from the other elements of our table have not been reported, it is interesting to notice that an energy level in ^{16}O at 0.83 Mv. is known to exist, since it is excited in a number of other nuclear reactions^{14,15}, and similarly an excited state of ^{12}C at 4.3 Mv. is known¹⁶. We are indebted to Mr. P. I. Dee for this discussion of the experimental data.

Finally, we would like to point out that, although one cannot consider the above evidence as convincing confirmation of the point of view we suggest, it is certainly incompatible with the K.U. theory, since

the existence of γ -rays shows that the observed curves must be superpositions of at least two simple spectra, whereas their shapes are not such as could be represented as sums of two K.U. curves with end-points differing by the energy of the γ -rays.

A New Form of the Baryteron Equation and Some Related Questions

It is known that the 2-component *spinors* introduced by Van der Waerden must be completed to 4-component quantities if linear transformation of their components by the complete Lorentz group including reflections is required. These quantities, often called 'Dirac wave-functions', will be called here 'four-spinors' or '*undors*' of the first rank*. Defining the reflection in the right way¹, it is possible to join to every four-spinor ψ another four-spinor² ψ^c , the components of which are linear combinations of those of ψ . This ψ^c is called the *charge-conjugated*³ of ψ . For if ψ is a solution of the Dirac equation for a positive particle,

$$m\psi = \beta(\epsilon - (\alpha\pi))\psi,$$

$$c\epsilon = \hbar(\partial/\partial t) - e\phi, \quad \pi = -\hbar\nabla - (e/c)\vec{A},$$

then ψ^c is a solution of the Dirac equation for a negative particle:

$$m\psi^c = \beta(\epsilon L - (\alpha\pi L))\psi^c,$$

$$c\epsilon L = \hbar(\partial/\partial t) + e\phi, \quad \pi L = -\hbar\nabla + (e/c)\vec{A};$$

vice versa ($\psi^c L = \psi$). Four-spinors, which are equal to their own charge-conjugated, we may call *neutrinos*. These quantities, which are equivalent to a two-spinor together with its complex conjugated, are not only useful in the so-called neutrino theory of light, but also Majorana's theory of *neutrons*⁴ may be summarized by stating that the quantized four-spinor of a neutral particle is a neutrino.

An *undor-calculus* analogous to tensor-calculus and Van der Waerden's spinor-calculus can be developed. An undor of the second rank $\Psi_{k,k'} (k, k' = 1, 2, 3, 4)$, that is, a quantity transforming like the product of two four-spinors, may be regarded then as consisting of a scalar, a pseudo-scalar and a pseudo-4-vector (the antisymmetrical part of $\Psi_{k,k'}$) and a regular

* Unds = Wave.

4-vector with an antisymmetrical tensor (its symmetrical part). So Kemmer's baryteron* field⁵ can be represented⁶ by one single symmetrical undor ($\Psi_{k,k'} = \Psi_{k',k}$). Denoting by ψ_p and ψ_n the wave-functions of protons and neutrons and by α, β and α', β' the Dirac matrices operating on k and k' , the baryteron equation^{7,8} is given in the following simple form:

$$2m_{\text{op}}\psi + 2if_{\text{op}}(\psi_{nk}\psi_{pk} + \psi_{nk'}\psi_{pk'}) = \beta(\epsilon - (\alpha\pi))\psi + \beta'(\epsilon - (\alpha'\pi))\psi. \quad (1)$$

The operator f_{op} , which operates on the arguments k and k' , becomes a constant c -number (f) only if the two constants f and g , occurring in Kemmer's equations⁵, would happen to be equal. As experiment seems to indicate⁹ that these constants do not differ very much, this formal argument for the advantage of equality of f and g seems to be interesting.

The electric charge-density and electric current are given by⁶

$$\rho = (e/8\hbar) \cdot \Psi^*(\beta + \beta')\Psi,$$

$$\vec{j} = (e/8\hbar) \cdot \Psi^*(\beta\alpha' + \beta'\alpha)\Psi.$$

The wave-function of *free* baryterons can be interpreted to some extent as the Dirac wave-function in the hole-theory of electrons. In both cases the same kinds of difficulty arise.

As for the complications occurring in baryteron theory^{5,6}, as well as in the quantum theory of the Maxwellian field^{10,11}, which are caused by the fact that some of the canonical equations of the field do not contain time derivatives, it is possible to develop a theory of quantization of mixed fields of Fermi-Dirac particles and Einstein-Bose quanta, in which the question of dealing with such complications is answered in a rather general way.

Details will be published elsewhere.

Exploration of the Sun's Disk and its Astrophysical Results

IN NATURE recently (Dec. 10, p. 1035), I took the opportunity, in connexion with the recent researches on practical relativity by H. E. Ives and G. R. Stilwell, to place on record that on principles scarcely anywhere denied now, a radiating atom, or system of atoms, falling free into the sun or describing a free orbit close around it should not experience any internal influence on the periods of its radiation, the

relativist factor due to the velocity produced being exactly balanced by another scalar direct effect of the field of gravitation itself: so that there would be left in evidence only the inevitable kinematic (Doppler) effect arising from mutual approach of the radiator and the terrestrial observer which, however, would soon rise to preponderance with increasing velocity.

I had forgotten at the time an array of important evidence bearing on this subject, in which I took close interest a year or two ago. I had been permitted by Mr. J. Evershed to learn in advance the results of his exploration of the variations of radiation periods on the solar disk, as it proceeded with greatly improved methods in his underground spectroscopic observatory in the Surrey hills, in continuation of researches in India by which he established an international fame for the solar observatory at Kodaikanal, above Madras. As he has now published preliminary results, in the *Observatory*, I can make use of this personal knowledge. Briefly, it was concluded that the observations could be fairly represented by an effect of the general type of pure relativity, such as might be due to the gravitating field of the sun but of about twice the Einstein predicted amount, combined, however, with a vector (Doppler) effect such as would arise from a *slow radial fall* of the absorbing system of atoms into the sun, about equal at its maximum, which is at the centre of the disk, to the Einstein factor, and, of course, vanishing at the limb, thus strongly favouring the important and natural result that only the systems of cooler atoms falling back into the sun (here at about 2 km. per sec.) produce the Fraunhofer absorptions.

(The familiar Evershed drift at sunspots, of the same order as the above, is tangential inward above and outward below, adjusted perhaps to compensate a much greater radial fall into the spot of the cooler absorbing gases such as would be required to damp off the continuous radiation of the photosphere below.)

If the outer layer of radiating atoms were subject to free fall into the sun, there would thus in fact be vanishing effect on periods, in accord with the general relations of relativity for isolated systems, as recognized and known definitely in England and America now for forty years. It follows that the forces of mutual atomic collision which float up the radiating atoms in the sun's atmosphere must provide a compensating factor that annuls, largely at any rate, what would be the result of free fall; for otherwise the total result for undisturbed falling atoms could not be null, as perhaps nobody would appear now to deny.

Another important result is to be signaled here. Astronomers are now accustomed to believe, on this type of spectroscopic evidence, that the dark companion of the star Sirius has a density, of value perhaps bordering on the fantastic, being about eight thousand times that of iron—though indeed this only involves that the atoms are twenty times closer packed in linear order. If the gravitational spectroscopic displacement is not solely of the Einstein type and is moreover mixed up, as here indicated, with effects due to other restraints and forces, there appears to be ample room, amid new atomic discoveries and ideas, for reconsideration of this decision as to abnormal material densities in stars.

Frequency Interpretation in Inverse Probability

DR. JEFFREYS implies in his letter in *NATURE* of September 17 (p. 535) that a prior probability cannot have a frequency interpretation. That there are several usages of the word probability is well recognized—it is a frequency, a mathematical result, a state of mind, or a degree of rational belief, depending on the circumstances. Jeffreys' point of view must be insisted on only when the conditions under which an experiment is performed are not subject to repeated sampling. However preponderant these circumstances may be in practice, it is important that consideration be given to problems in which the frequency interpretation does apply to the prior probabilities, since the frequency interpretation is the only one that is operationally verifiable.

A problem for illustration is this. A box has had 10 balls transferred to it by a blindfolded man from an auxiliary container holding equal numbers of black and white balls, the contents of the auxiliary container being kept constant and thoroughly mixed by an assistant. Then an experiment is carried out on the box; the blindfolded man draws a ball from the box and returns it, the assistant noting the colour of the ball and shaking the box before the next draw. The blindfolded man makes five such draws from the box (each with replacement); four of them show black and one white. What are the probabilities of the various possible contents of the box? (Reworded from an example given in Fry's "Probability", Van Nostrand, 1928, p. 123.)

The stirring and blindfolding, we shall presume, create randomness and cause the point binomial to be applicable in the frequency sense, both with regard to the 10 balls put into the box and the 'experiment' of drawing 5 balls with the replacement from the box. The equal numbers in the auxiliary container have only the effect of making $p = q = \frac{1}{2}$ in the binomial expansion of $(q + p)^n$, and any other proportions would do as well. We have at once from the binomial expansion the term $\binom{n}{r} q^{n-r} p^r$ for the

prior probability that r white balls found their way into the box in the first place ($n = 10$; $r = 0, 1, 2, \dots, 10$; $p = q = \frac{1}{2}$). Now if there are r white balls in the box, the probability that five draws, with replacement, will show 4 black and 1 white is $\binom{5}{1} \left(\frac{r}{10}\right) \left(\frac{10-r}{10}\right)^4$, whereupon the simultaneous probability that r of the 10 balls in the box are white, and that the 'experiment' should show 4 black and 1 white, is the product of these two expressions, namely,

$$\binom{10}{r} \left(\frac{1}{2}\right)^{10-r} \left(\frac{1}{2}\right)^r \binom{5}{1} \left(\frac{r}{10}\right) \left(\frac{10-r}{10}\right)^4.$$

If we now 'normalize' this product we shall have, after cancelling common factors,

$$p(r) = \frac{\binom{10}{r} \left(\frac{r}{10}\right) \left(\frac{10-r}{10}\right)^4}{\sum_{r=0}^{10} \binom{10}{r} \left(\frac{r}{10}\right) \left(\frac{10-r}{10}\right)^4}$$

for the 'posterior probability' of there being r white balls in the box. Plotted against r , the two functions $\binom{n}{r} q^{n-r} p^r$ and $p(r)$ give the two sets of points shown in the accompanying figure (for clarity the points in each set have been joined by a broken line).

The frequency interpretation of the prior probability $\binom{n}{r} q^{n-r} p^r$ is as follows: at a single filling of the box there are either, for example, 3 white balls in the box or there are not; that is, the probability of there being 3 white balls in the box is either 0 or 1, no intermediate value being admitted. There is no talk of the probability of there being r white balls in the box, in the frequency sense, unless the box is filled *many times* from the auxiliary container under conditions that produce random results in the box content. If this is presumed, then after a large number of fillings, a record of the box content would show $\binom{n}{r} q^{n-r} p^r$ for the relative frequencies of r white balls getting into the box ($r = 0, 1, 2, 3 \dots 10$); we can assert this because the drawings are 'at random',

which I take to mean nothing more nor less than the validity of the frequency interpretation of the binomial expansion. The term $\binom{n}{r} q^{n-r} p^r$ is ordinarily called the 'prior probability' of r white balls, but a better name might be *unselected* probability, and it is so labelled in the figure: it is unselected because *all fillings have been counted* in the record, that is, no selection from the record has been made.

Now for the frequency interpretation of $p(r)$, let us suppose that at each filling of the box, before it was emptied and filled again, the 'experiment' of drawing 5 balls was performed and the results noted. Then for each occasion upon which 10 balls were put into the box in the prescribed manner, we have a notation in our record showing, first, the number of white balls in the box (0, 1, 2 . . . 10), and secondly, the result of the experiment (0 white and 5 black, 1 white and 4 black . . . 5 white and 0 black); and there are supposedly some huge number of these notations. If we now strike from this record all the notations *except* those for which the immediate experiment yielded 4 black and 1 white, we shall find that the relative frequencies (probabilities)

of r white balls in the box, in *this selected class*, is $p(r)$. The denominator of $p(r)$ is a mathematical device for accomplishing this selection. $P(r)$ is called the 'posterior probability' of r white balls in the box, but a better name would be the *selected* probability, and so it is labelled in the figure. Thus we see a frequency interpretation for both the prior and posterior probabilities, and we see also from the frequency point of view the distinction between them—in the former the probability of r white balls is computed without selection, and in the latter, with selection.

From the figure, it is evident that the box content that yields 4 black and 1 white most frequently in the 'experiments' is 6 black and 4 white. At the same time it is interesting to note that this particular box content will yield 3 black and 2 white in five draws more frequently than it will yield 4 black and 1 white, and that the optimum box content for 4 black and 1 white is 8 black and 2 white.

An Electro-Chemical Theory of Salt Absorption and Respiration

THE surface layer of wheat roots which are put in distilled water behaves like a membrane charged with hydrogen ions in a concentration of about $10^{-3} N$. ($pH = \alpha. 3$)¹. If a neutral salt is added to the water, the metallic cations are adsorbed in exchange for part of the hydrogen ions. As a consequence, the actual pH of the protoplasmic membrane increases; in a $10^{-3} N$ solution of potassium chloride it is about $pH = 6$. If the solution has $pH = 7$ a potential difference of about 58 mv. occurs. The protoplasmic membrane is then negative relatively to the solution. This negative charge is the normal state of the absorption cells of the root tissue.

Owing to the negative charge of the protoplasmic membrane, cations pass without difficulty into the protoplasm, whereas the uptake of anions requires energy supply. Oxidation processes seem to supply this energy.

Oxidation implies a decrease of the negative charge of the oxidized substance. According to Le Chatelier's principle, oxidation processes will be promoted in the surface of the protoplasm of root cells. Respiration is the oxidation of carbohydrates by free oxygen effected in special redox systems of the living cell. If such a respiration system is put into action by the potential difference between the protoplasmic membrane and the medium, it will act electro-chemically as if electrons (anions) were thrown out into the solution. In exchange for these amounts of negative electricity that traverse the outer cell boundary, anions will move in the opposite direction from the medium into the cell.

This theory of 'anion respiration' is supported by a large number of observations made in my laboratory during the course of the last six years. A few of them are described here.

The respiration intensity of roots which are surrounded by distilled water always attains very high values². Potential measurements¹ show a correspondingly high negative potential of the root surface. It attains values of -150 to -200 mv. In this case, the anion respiration will of course be 'idling', because there are no anions to absorb from the distilled water, except very small amounts of OH^- and HCO_3^- .

The relation $\frac{\text{respiration}}{\text{anion absorption}}$ shows high values when the salt concentration in the medium is low, and decreases with increasing concentration. The potential difference between the root and the medium decreases also with increasing salt concentration. In one series the relation $\frac{K \text{ absorb.}}{NO_3 \text{ absorb.}}$ attained the values 0.77 in a 0.001 N. KNO_3 solution and 0.43 in a 0.01 N. solution. The initial potential difference was ca. -70 mv. in the diluted and ca. -25 mv. in the more concentrated solution. More energy is needed to absorb anions in the former case.

Extensive experiments² indicate a sort of quantitative relation between the amount of anions absorbed by the root and the respiration intensity during the same period. The following equation was formulated:

$$R_t = R_f + kA,$$

where R_f is a fundamental or 'minimum' respiration that occurs independently of the mechanism of anion absorption; kA is the anion respiration, which is a multiple k of the anion absorption A ; R_t is the total respiration measured in the experiments. The existence of a 'fundamental respiration' is proved by the fact that its intensity is unaffected by agents, for example, potassium cyanide, which check the anion absorption. The anion respiration is an oxidation mechanism which is regulated by the negative electrical charge of the protoplasmic membrane and it supplies apparently the energy for the absorption of anions against the potential gradient.

The above equation represents only the outlines of the process, for other factors also influence the surface potential of the protoplasm. Thus the coefficient k is a constant only if other factors, for example, the kind of cations in the solution, are constant too. From what has been said about salts and surface potential of the protoplasm, it is evident that the exchange power of the cations partly determines this potential. Bivalent ions have a larger exchange power than monovalent ones, and therefore, in equimolar concentration, depress the potential difference more. On the other hand, ions of high exchange power are less mobile in the protoplasmic colloids; their retention in the solution increases again the negative potential in the protoplasmic membrane. It requires more energy, of course, to absorb anions from a solution if cations are held back than if they are absorbed in similar amounts too. Consequently absorption experiments

show that the relation $\frac{\text{anion respiration}}{\text{anion absorption}} = k$ gives higher values for salts of bivalent cations, for example, Ca^{++} , than for potassium salts. For the same reason, k is higher in a barium salt than in a calcium salt (Ba^{++} is less mobile than Ca^{++}). If the mechanism of the anion respiration is regulated by the negative charge in the protoplasmic membrane, and if this charge, as measurements show, is a product of the relation $\frac{cH \text{ of protoplasmic membrane}}{cH \text{ of the medium}}$, the cH value of the

medium and all factors which determine this will be included in the complex of conditions which determine the value of the coefficient k in the above equation. Apart from the relative absorption velocity of cations and anions just mentioned, one end-product of the respiration, HCO_3^- ions, is an important regulator of the pH of the medium. The aeration of the medium

will consequently be an important factor, apart from the fact that the oxygen supply which controls the respiration also depends upon the aeration. The somewhat curious situation will then occur that a very effective aeration is a drawback for intensive anion uptake, because the carbon dioxide left in the solution helps the protoplasm to overcome the resistance to anion absorption.

The theory of anion respiration of which we have here given an outline refers to cells with a pronouncedly acid protoplasmic membrane. Such a membrane seems to be characteristic of plant roots. Other kinds of cells might behave differently. I recall in this connexion the interesting observations on the skin of frogs³. If the charge of the root cells is changed to positive by holding them in a ca. 10^{-2} N. solution of a strong acid, they die within a few minutes. Also in very concentrated salt solutions ($> 10^{-1}$ N. KCl) the charge of the membrane will be changed into positive; but the cells then live longer. Such media are by no means normal. On the other hand, one can easily conceive that cells of a normally positive charge relatively to the medium might exist. Such cells will be able to absorb anions without any extra energy supply, but the absorption of cations needs energy supply. This is a speculation so far, because our experience of the interference of reduction processes in ion absorption is very limited. From the point of view of electro-chemistry, reduction processes diminish the positive charge. Attention is here directed to the interesting results of Arens in the polarity of leaf cells during photosynthesis⁴. Potential gradients in protoplasmic boundaries are probably of fundamental importance both in the metabolism and in the translocation of substances within the organism, as well as in the absorption and excretion of ions. From this point of view the investigations in the ion absorption of plant roots may have a wider application.

Reduction of Carbon Dioxide with Molecular Hydrogen in Green Algae

A VIGOROUSLY growing pure culture of the alga *Scenedesmus* sp. D.3 is suspended in a hundredth molar (1/100 M.) solution of potassium bicarbonate and kept for six hours in the dark in an atmosphere of hydrogen containing 2 per cent carbon dioxide. Shortly before the last traces of oxygen in the vessel have disappeared by way of respiration, the cells begin to absorb hydrogen. The amount of hydrogen absorbed in this reaction varies with the condition of the algae. After this absorption has stopped, practically no further gas exchange is observed. If the light is now turned on, no evolution of oxygen can be detected but the algae begin to absorb hydrogen instead. The process has a measurable induction period, but thereafter it proceeds at a steady rate. This phenomenon is strikingly similar to the reduction of carbon dioxide with molecular hydrogen brought about by purple bacteria. That this absorption of hydrogen by the green algae is connected with the

reduction of carbon dioxide can be shown by the same method which enables one to establish the ratio H_2/CO_2 in purple bacteria¹. The algae are suspended in a slightly acid phosphate buffer, treated with hydrogen in the dark, and then illuminated until all carbon dioxide stored or produced by fermentation has been used up in photosynthesis. Addition of a known amount of carbonate at this point is followed by a rapid uptake of hydrogen, the quantity of which exceeds the ratio $2H_2$ for $1CO_2$ found in purple bacteria. In *Scenedesmus* this ratio often reaches a value of about 3.

The reaction between molecular hydrogen and carbonic acid in green plants is affected in a peculiar manner by the light intensity. Up to a certain threshold the rate of hydrogen absorption is proportional to the light intensity and at constant intensity, when both reactants are present in excess, the reaction proceeds at a constant rate. If, however, the light exceeds a certain limit of intensity, the absorption of hydrogen stops and after a few minutes normal photosynthesis is in full activity with the production of oxygen.

This effect of light of too high intensity cannot be reversed merely by subsequent reduction of that intensity; a slow dark reaction is necessary to re-establish the bacterial type of light metabolism in green plants.

In the absence of light, 'hydrogen-treated' algae are able to catalyse the 'oxyhydrogen' reaction, provided the tension of oxygen is held below a certain limiting value. Oxygen at a higher pressure inhibits the oxidation of hydrogen completely; once it has been inhibited, the reaction cannot be immediately restored by lowering the oxygen pressure. For reactivation an incubation period under anaerobic conditions is necessary. The inhibiting effect of oxygen on the 'oxyhydrogen' reaction in *Scenedesmus* is very similar to the phenomenon in *Acetobacter peroxidans*².

These two observations in *Scenedesmus* supplement each other inasmuch as the reduction of carbon dioxide with hydrogen can be explained by the oxyhydrogen reaction, the catalytic system of the latter reaction being apparently able to use the molecular oxygen produced in photosynthesis at low light intensities. The reaction rates, however, suggest an alternative explanation. Under the conditions of the experiments the oxyhydrogen reaction in green plants may be catalysed by the same enzyme system which normally liberates oxygen in photosynthesis. When completely reduced, the enzyme would not react as a catalase but as an oxidase and a peroxidase. This action of the catalyst would be practically the same in green plants and in purple bacteria. The alternative explanation therefore brings photosynthesis by purple bacteria into accord with that in green plants. Added support to this hypothesis is found in the papers of Keilin and Hartree³ and of Stern⁴ on hydrogen peroxide catalase, from which it appears that catalase will occasionally act as a peroxidase.

Further Evidence for the Lamarckian Theory of the Cause of Evolution

THE death of Prof. William McDougall marks the end of an epoch in the history of biology. Prof. McDougall attained world-wide fame as a brilliant experimental psychologist, but his equally important work on the heritability of acquired habit has been, I think, for the most part overlooked. He experimented on rats, and he showed that when rats were forced by unpleasant experience to acquire a habit, they produced offspring which acquired the habit more readily than did their parents until, at the end of nine years, they acquired the habit at the first contact with the unpleasant experience.

The late Miss Dorothy Sladden (whose work has periodically been noted in NATURE) also, like McDougall, was engaged in experiments on the heritability of acquired habit, though she knew nothing of McDougall's work. When she died her work, like that of McDougall, was complete, but the final and conclusive part of it was embodied in jottings in note-books and columns of figures. My former colleague, Mr. H. M. Hewer, has edited these notes and published his results, which were noted in NATURE¹.

As Miss Sladden's experiments were of a much simpler type than those of McDougall, a very brief account of them may be given here. She used the stick-insect *Coroniscus morosus*, a native of South India, which in Great Britain normally feeds on privet. This insect was subjected to periods of semi-starvation, each lasting two days, when it was offered ivy for food which it detested. At the end of each period it was revived by a leaf of privet. Each of these ordeals was called a 'presentation'. The overwhelming majority of the insects would not accept ivy until the fifth presentation, and some even held out until the tenth presentation. These insects are parthenogenetic and when their eggs were collected and bred from, it was found that they accepted ivy at an earlier presentation than did their parents until at the end of five years they took ivy at the first opportunity. Thus Miss Sladden and Prof. McDougall between them have adduced evidence in support of the hypothesis that the acquired habits of one generation are passed on to the next.

Of this I may give two examples. The Didsbury Institute informs me that the effort to transplant sea-land cotton from islets off the coast of Carolina to other parts of the world has resulted in failure. In a few years the transported cotton reverts to the native stock. On the other hand, Marquis wheat, which has doubled the Canadian wheat crop owing to its ability to survive 'summer frosts', has been proved to be a northern Russian race which has gradually adapted itself to the rigours of a subarctic climate. 'Mutants' only persist when cultivated under the exact conditions of soil in which they made their appearance; further, they become progressively weaker and liable to disease.

The alternative hypothesis as to the origin of species has been that these originated from the sports familiar to us in the garden and farmyard which are the source of some of our most valuable domesticated animals and plants. But there are two difficulties about this hypothesis: first, Mohr, whom the late Dr. Bateson called the first geneticist in Europe, has shown that all sports are physiologically weaklings and could never survive in the open; and secondly, that when such sports are returned to the wild in a

place where their natural enemies are absent, in forty-fifty years they revert to the condition of the wild ancestor. Further, though it might be supposed that the study of these sports is of prime importance to the farmer, experience shows that this is not so. Thus the work of these two experimenters has raised Lamarckism from the rank of an hypothesis to the status of a proved fact; for the first time evolution has been experimentally demonstrated in the laboratory.

The Dead Language of Science

PROF. F. E. FRITSCH¹ complains of the many new terms encumbering a recent German text. We must all sympathize with his view. But is there not a worse evil in our midst, one to which long use has inured us? I mean the constant reiteration of dead terms, of decayed verbiage. Prof. Fritsch disinters a sample, the word 'spireme', and discusses its use. This word originally (in 1882, according to Wilson) referred to the threads seen in the prophase of a nuclear division, mitosis or meiosis. In England and America it was connected with *Oenothera* in 1907, and became known as the 'continuous spireme' of meiosis. This connexion ended after a period of some confusion in 1932, when the spireme suddenly passed away. By 1934 it had disappeared from Sharp's "Introduction to Cytology". It is no doubt from the *Oenothera* connexion that Prof. Fritsch recollects the word and in a meaning to which it was never restricted elsewhere. In Germany its last technical use is found in 1934 (Geitler, "Grundriss der Cytologie"). There also it has since disappeared (Geitler, 1938, "Chromosomenbau").

By technical use, I mean use by those who are handling the material or studying the process every day. There are many words, dead words, found in text-books for elementary students which are never used in technical practice. This fact is obvious as soon as it is pointed out. Take the word 'karyokinesis'. It is never used either in speech or writing by those who study nuclear division, and was effectively superseded by 'mitosis' more than fifty years ago. Yet almost every English text-book mentioning cytology tells its readers that nuclear division is known as karyokinesis or mitosis; and every student commits to memory this unnecessary fiction—usually, it must be admitted, along with a correspondingly erroneous account of the process. Other sciences could tell the same tale.

There are many words in text-book currency which fall into this phlogiston group. Words like 'heterotypic mitosis', 'nuclear reticulum', 'telosynapsis' and 'xenia' are the dead or dying remains of past misunderstandings—merely useless lumber. There are many others not yet dead, however, which have no proper place in text-books. Words as cacophonous as 'obdiploetemony', as obscure as 'arrhenotoky', as superfluous as 'phragmoplast' must give the specialist pause.

It is to be feared that men of science in all countries will often, in inventing new terms, create hideous, meaningless and unnecessary words. It is also to be feared that compilers of text-books will often be afraid of appearing ignorant if they neglect to record

these verbal discoveries. But it is the business of these writers to sort out the words which will convey the information necessary for doing certain work. Words that do not fulfil this use should always be rejected from the text and segregated in a glossary for the inspection of the learned, not for the confusion of the learner.

The Prehensile Paw of the Giant Panda

IN NATURE of January 28, p. 157, Prof. Wood Jones, in his description of the prehensile digit in the fore paw of the giant panda, stated that the radial sesamoid bone has a special muscular arrangement making it movable so as to act as a true thumb it "usurps the place of the true thumb and simulate all its movements".

This remark must have been based, I think, upon an examination of the paw with the skin removed because in the skeleton of the foot, as has been known for years, the lengthened sesamoid bone in question looks, in a measure, so like an additional digit on the inner side of the foot that anyone might be excused for suspecting that it projects like a thumb and is capable of considerable lateral movement, giving it a prehensile function. It has scarcely any such function. It is enveloped in the skin of the foot, like the metacarpal bones, and is quite invisible the only indication of it, as is also well known, being the enlarged, cushion-like extension of the plantar pad which covers its apex. The use of this pad was unsuspected until the living animals were observed in the Zoological Gardens. On the dead specimen, found it capable of only slight movement; but it acts as an accessory to the prehensile power of the first and, to a lesser degree, of the second digit. When these are normally flexed in a vertical plane their terminal pads come into contact with the elevated portion of the plantar pad and constitute a grasping organ. The mechanism is exactly comparable to that produced by bringing the tips of the first and second fingers on to the ball of the thumb in the human hand.

Turtles in the English Channel

IN his interesting letter on the occurrence of turtles in British waters, Mr. H. W. Parker¹ has suggested that their presence in the English Channel may be an indication of the drift of warm surface water up-Channel. There is another possible explanation. Evidence has not been lacking during recent years that there has been an extension of the distribution of many warm water animals to the far north (see, for example, Stephen²). Recently also the unusual capture of a flying fish, *Cypselurus heterurus*, in Oslo Harbour in 1937 has been recorded by A. Wollbeaek (see Brunn³); this is the first record of a flying fish at Oslo since 1848.

While there is no indication that the water temperature in the Channel region is any higher than normal there can be no doubt that warm water has been penetrating farther towards Arctic regions. This will

flow an extension of the northern boundary of certain animals, and it is perhaps natural to suppose that, allowing this extension, the centres of distribution may also have shifted more to the north. Such an extension might thus bring turtles into a region in which westerly winds would tend to drift them up the English Channel, without necessarily a passage of any considerable body of water in the same direction.

Formation of Native Lead under Laboratory Conditions

THE conditions which may have governed the formation of native metals in non-igneous rocks are not always readily reproducible in the laboratory owing to the difficulty of performing experiments

requiring many years for completion. An observation made during the reconstruction of the Plymouth Laboratory may be regarded as an experiment of fifty years duration.

The slate back, sides and bottom of the aquarium tanks in the main laboratory, built in 1888 and dismantled recently, were cemented with a lute composed of white lead with some red lead and linseed oil. During fifty years, pockets and seepage channels have formed into which sea-water, rich in organic matter, has crept. The oxides and carbonates of lead have been reduced, in some places to black lead sulphide. More remarkable has been the further reduction, in other pockets, giving rise to inclusions of metallic lead answering to the usual analytical tests. When first exposed these had rough but bright metallic surfaces, similar in appearance, both to the unaided eye and under the microscope, to commercial lead which had been etched with dilute acetic acid.

Points from Forgoing Letters

INFRA-RED absorption in the region of 3μ of *o*- and *m*-methoxybenzoic acids in carbon tetrachloride has been investigated by Dr. J. J. Fox and Dr. A. E. Martin. These compounds show a small band attributable to OH vibrations in the monomer, and a broad band at 3.4μ due to OH vibrations in the dimer. In addition, the *ortho*-compound has an intense band at 2.974μ ascribed to intramolecular association of the OH group.

Prof. H. A. Bethe, F. Hoyle and Prof. R. Peierls state that the experimental evidence on β -disintegrations, except for the shape of the energy spectrum, supports Fermi's original theory rather than its modification by Konopinski and Uhlenbeck, and that one can account for the shape of the spectrum by postulating the emission, in some disintegrations, of γ -rays of suitable energy and intensity. The existence of such γ -rays is in some cases confirmed, in others not ruled out, by the experimental evidence.

In the same way as vectors are generalized to tensors, Dirac wave-functions may be generalized to 'undors' and a consistent under-calculus may be developed, according to F. J. Belinfante, who presents the equation for heavy quanta (baryterons) in a concise form closely analogous to the Dirac equation for the electron.

Referring to the variations observed by J. Evershed in the radiation periods on the solar disk, Sir Josepharmor states that they support the view that the forces of mutual atomic collision which float up the radiating atoms in the sun's atmosphere must provide a compensating factor that annuls any influence on the period of radiation which would otherwise be reduced by the free fall. If the gravitational spectroscopic displacement is not solely of the Einsteinian type but is influenced by other forces, as indicated, it may be necessary to reconsider the enormous densities which have been calculated for certain stars such as the dark companion of Sirius.

Dr. W. Edwards Deming takes the view that there are circumstances in which prior probabilities have a frequency interpretation, and describes an experiment in which the frequency interpretations of the prior and posterior probabilities are contrasted: the former, he states, are probabilities associated with the circumstances in which all the experiments are performed, and might be termed *unselected*. The posterior probabilities also refer to the circumstances of the experiment but not to all experiments; they refer to the selected class, namely, those that had a particular result, all others being excluded, and might be designated as *selected* rather than posterior.

Prof. H. Lundegårdh develops an electrochemical theory of salt absorption according to which cations pass without difficulty into the protoplasm owing to the negative charge of the protoplasmic plant membrane, whereas the uptake of anions requires a supply of energy, which is provided by oxidation processes. The author remarks that this applies to the plant cells so far investigated and that other cells may behave differently.

Dr. H. Gaffron states that by prolonged anaerobic treatment in an atmosphere of hydrogen green algae acquire the capacity to reduce carbon dioxide with hydrogen when illuminated. No oxygen is developed. This new light reaction may go on for a long time at low light intensities but stops immediately at higher intensities, the absorption of hydrogen then changing into the normal production of oxygen.

The work of Prof. W. McDougall and Miss Dorothy Sladden is quoted by Prof. E. W. MacBride as affording conclusive evidence that acquired habits of one generation may be passed on to the next. Prof. MacBride reiterates his view that this is the main mechanism of evolutionary change, and maintains that 'mutants' are physiologically weaklings which tend to return to the ancestral type.

Research Items

Archaeological Excavations at Eastburn, Yorkshire

IN the making of a new aerodrome at Eastburn on the Yorkshire Wolds, near Driffield, skeletons were found which on examination proved to be of iron age type; but no pottery or metal was found with them to determine their age. Later, in the course of constructing a hangar, some fifty iron age graves were exposed. The site and the relics recovered have been described by Mr. Thomas Sheppard (*Hull Museum Publications*, 197; 1938). Each tumulus was very clearly indicated in the white chalk gravel by a circle representing a slight trench on the outside of the mound, and a dark, usually squarish, place in the centre of the circle, three to four feet across, which contained a skeleton or occasionally two skeletons. The bones were so decomposed that in three instances only was it possible to remove sufficient of the skull for examination. No pottery or iron was associated with the burials, excepting a single iron brooch or fibula of the involuted type. This type is considered by Sir Arthur Evans to date from 300 B.C. A fragment of a similar brooch was brought to the excavator. It had a knob of red glass still attached by a metal stem, of which the head is apparently copper. A typical iron age pot larger than those from the Danea graves was also found. A year later further discoveries were made, including a female skeleton in remarkably good condition. Three earthenware vessels were also found, of which one, a small vessel with a slightly curved depression between lip and shoulder, is the only one of its kind found in that condition in East Yorkshire. The largest of the three is an example of coiled technique. This vessel and another each contained the humerus of a pig. Among the iron objects found were a leaf-shaped spearhead and a remarkable iron sword 28 inches in length. Its handle had been mounted with horn and there were traces of a wooden scabbard. On the arm of a female skeleton was a bronze bracelet of great beauty with two decorated bands of cable-like design. Roman and Anglo-Saxon relics also occurred on the site.

Recent Research on Cancer

THE thirty-sixth annual report of the Imperial Cancer Research Fund, which has just been published, is the first to appear since the Fund moved into new laboratories at Mill Hill. It summarizes the work carried out during the last year on carcinogenesis, the nature of tumour viruses, the action of radiations and of hormones and the properties of tissue cultures. Dr. F. R. Selbie and Dr. C. Foulds have extended knowledge on the carcinogenic action of radioactive substances. They obtained tumours at the site of injection with thorotrast (a colloidal preparation of thorium oxide) in rats, mice and guinea pigs. There would seem to be little doubt that thorotrast should not be used clinically on account of its possible carcinogenic action on man. Dr. W. Cramer and Dr. E. S. Horning investigated the antagonism between oestrogens and the hormones of the pituitary acidophil cells. In a preliminary experiment they have been able to inhibit the spontaneous incidence of mammary cancer in mice by treatment with preparations of the pituitary thyrotropic

hormone. If fibroblasts and sarcoma cells are grown as tissue cultures in plasma, the sarcoma cells liquefy the clot more rapidly than do the non-malignant cells. Dr. R. J. Ludford has found that some trypanocidal agents such as Trypan Blue and Bayer 205 promote this liquefaction of the clot by cells, but this action is not specifically associated with tumour cells. Mr. H. G. Crabtree, in conjunction with Dr. L. H. Gray of the Mount Vernon Hospital, found that the ability of isolated tumour tissue and isolated retina to produce lactic acid are both equally inhibited by equivalent doses of γ -radiation, β -radiation or X-radiation when applied *in vitro* at low temperature.

Tubercular Allergy without Infection

F. R. Sabin and A. L. Joyner (*J. Exp. Med.*, 68, 659; 1938) found that guinea pigs could be rendered hypersensitive to tuberculo-protein by small, repeated, intradermal injections of active tuberculo-protein. The process of sensitization could be accelerated by the addition of tuberculo-phosphatide to the protein, so that the reactions became indurated and necrotic and closely simulated tuberculous disease. Injection of active tuberculo-protein induced a new formation of monocytes and some epithelioid cells, and the addition of phosphatide to the protein brought about a massive formation of epithelioid cells. The writers regard the intradermal route as the best for these sensitizations probably because it provided the largest dose per cell of the sensitizing agent. They compare the degree of sensitization artificially obtainable by the synergic action of tuberculo-phosphatide and tuberculo-protein to the degree of sensitization naturally occurring in tuberculous animals.

Reactions of House-flies to Light of Different Wave-lengths

J. W. MACBAIN CAMERON, of Macdonald College, Montreal, has recently described experiments which were conducted with the object of testing the reactions of house-flies to different wave-lengths of light (*Canadian J. Res.*, 16, 307; 1938). The insects were reared on an artificial medium and tested by means of different wave-lengths of spectral light obtained from a quartz-mercury vapour lamp. The range of the spectrum tested was from 3022 Å. to 5780 Å. and the lines were made of approximately equal intensity throughout. In addition, 5461 Å. and 4078 Å. were tested at several other intensities. The comparison standard, which was used in all cases, was white light obtained from a tungsten filament frosted bulb. Flies to be tested were removed from breeding cages ten hours before the tests began and were kept in darkness until used. It was found that the house-fly is much more strongly stimulated by ultra-violet light of wave-length 3656 Å. than by any other part of the spectrum tested. The influence decreases as the longer wave-lengths are reached and also on the short wave-length side of the peak. The available spectrum extended as far as 3022 Å. into the ultra-violet, and at this point there is still an attractiveness greater than that exercised either by yellow or green.

Original Home of the Coco-nut

UNDER this title P. V. Mayuranathan, curator of the Botany Department, Government Museum, Madras, has published an interesting discussion of this subject (*J. Bombay Nat. Hist. Soc.*, 11, (2); September 1938). His paper examines particularly the question of the antiquity of the coco-nut in India, and whilst discussing previous suggestions as to the original home and the subsequent course of distribution of this palm, it pays particular attention to the geological history of the regions under discussion and supplements botanical evidence with that drawn from philological and ethnological sources. So old is the coco-nut in India that the Arabs from early times called it the Indian nut. On the other hand, *Cocos* is an American genus with no other living representative of that genus anywhere except in the continent of America. The author's solution is that it originated in that ancient Papuan land which included the island continent of New Guinea as we know it to-day; from there the strong eastward current during the north-east monsoon carried it through the Straits of Malacca into the Bay of Bengal, and primitive man brought it over to the shores of India. The discovery of fossil *Cocos* in the Pliocene deposits of New Zealand would be in accord with this view.

Northern Californian Earthquakes during 1937

As is well known, California forms part of that well-established ring of instability, the circum-Pacific circle, and it was in the Californian region that on April 18, 1906, occurred the great earthquake which wrought havoc in San Francisco and caused such remarkable displacements along the San Andreas rift. During 1937 there was no shock so great as this one, but there were approximately 277 earthquakes and earth tremors of varying intensity. Their intensities and distribution have been examined by Perry Byerly and John N. Adkins (*Bull. Seis. Soc. Amer.*, 28, No. 4, 263-268; Oct. 1938). One hundred and forty earthquakes were sufficiently well recorded at the various stations for their seventy-five epicentres and initial times to be determined, and for these a map has been drawn by the authors. The epicentres form a broad band parallel with the coast-line with, as in 1936, a region comparatively free from epicentres between Humboldt County and San Francisco Bay, a very active region east of Monterey Bay, and very few epicentres along the San Andreas Fault between Monterey Bay and San Francisco. Compared with 1936 there was increased activity in the region east of San Francisco Bay. There appears to have been also a line of epicentres roughly at right angles to the coast, approximately through the towns of Greenfield and Merced. Seventeen earthquakes occurred in known regions the epicentres of which could not be located accurately owing to poverty of data, and the following observatories recorded shocks not felt by persons or recorded at other observatories: Berkeley, 26; Mount Hamilton, 28; Palo Alto, 38; San Francisco, 2; Ferndale, 8; Fresno, 3. Finally, fifteen shocks were recorded at more than one station, not felt by people and insufficiently well recorded for their epicentres to be located.

Analysis of Mine Dusts

PAPER No. 101, on the analysis of mine dusts, by A. L. Godbert, Safety in Mines Research Board (H.M. Stationery Office, London, S.W.1, 1938. 1s. 6d.) gives an alternative method of

determining the carbon dioxide contents of mine dusts containing carbonates and a method of determining separately the free and combined water in mine dusts containing gypsum. These data are important in relation to the suppressing action on inflammation of coal dusts known to result from carbonates and combined water.

Density Condensation of Cepheid Variables

ZDENĚK KOPAL has recently published the results of his research on 88 δ Cephei stars and 30 variables of the RR Lyrae type (*Mon. Not. Roy. Astro. Soc.*, 99, 1; Nov. 1938). He makes use of the well-known period-luminosity and mass-luminosity relations and also assumes that the cepheids radiate like black bodies, from which two tables are compiled showing the following results: P , the period of pulsation; Sp , the spectral type; $\log T_*/T_\odot$, $T_\odot$ and T_* , referring to the temperatures of the sun and star respectively; absolute visual and also absolute bolometric magnitudes; $\log \sqrt{\rho m}$; $\log P\sqrt{\rho m}$, ρ being the density. Although it has been assumed for a considerable time that P has nearly the same value for all cepheids, it is shown in the tables that there is practically no foundation for this assumption. There is a well-defined relation between $P\sqrt{\rho m}$ and the spectrum, and it seems that there is a close connexion between the density condensations of cepheids and their spectral class. This, of course, depends on the hypotheses involved in the present state of the pulsating theory being correct. There is a gap in the values $P\sqrt{\rho m}$ between the long- and short-period cepheids at spectral type $F5$, and it is suggested that the sudden change of $P\sqrt{\rho}$ takes place when a certain temperature has been reached so that there is an alteration in the ratio of specific heats. This explanation, however, is ruled out, and a real change of density condensation is believed to take place. This affords good reasons for the assumption that the long- and short-period cepheids are of essentially different structure.

A Comparison Sequence for Nova Lacertæ

S. A. Mitchell and C. A. Wirtanen have published a paper with this title which will prove useful to variable star observers (*Mon. Not. Roy. Astro. Soc.*, 99, 1; Nov. 1938). The paper is the outcome of an informal meeting of the leaders of the American, British and French variable star associations during the sessions of the I.A.U. held at Stockholm last year. A request was made that the Leander McCormick Observatory should publish the magnitudes and co-ordinates of sequence stars for long-period variables that have been determined since *McCormick Publications*, 6, appeared in 1935, and a special request was made for Nova Lacertæ, No. 2. A table gives visual and photo-visual magnitudes for thirty stars with their co-ordinates, and, assuming equal accuracy for each method, the probable error of one magnitude is 0.02 magnitude. Three of the faintest stars of the sequence, magnitudes 14.6, 15.0, 15.3, have no photovisual magnitudes and these have been observed independently by W. H. Stevenson. Mitchell, using the 26-in. refractor, made visual sequences of grade estimates, and it will be shown in the forthcoming variable-star publication that the scale of his visual magnitudes agrees very closely with the international photovisual system to which the values of Nova Lacertæ are reduced.

Science and Philosophy

IN a Friday evening discourse delivered at the Royal Institution on December 2, the Right Hon. Viscount Samuel discussed the importance of obtaining closer co-operation between science and philosophy than there has been in the past. The scientific worker, intent on special problems, has tended to ignore the need to examine the general principles on which his studies rest. Separation has come from the other side too. Nineteenth century philosophy of the idealist tradition went on its way regardless of science, with disastrous consequences. The question is not a purely academic one. At the present time, he said, "every land resounds with the tramp of armies, and the air throbs with the droning of their aircraft. Behind the armies are the dictators or the parliaments. Behind them are the political creeds—Communism, National-Socialism, Fascism, Democracy. And behind the creeds are the philosophers—Marx and Engels; Hegel, Nietzsche, Spengler, Sorel and Croce; Mill and the other protagonists of liberty. Some of the creeds, it is true, are anti-intellectual; but irrationalism also is a philosophy of a kind".

If philosophies of this kind are to be avoided, a reasonable basis must be found for ethics and religion in place of the confusion and uncertainty now prevailing. The first step in this direction is for the philosopher frankly to accept the main conclusions and point of view of science. In particular, he must admit that the universe exists independently of human thought. Men and their thoughts enjoy no special privilege except as parts and products of this universe. The realist tendencies that are noticeable in recent philosophy in Great Britain and in the United States are therefore to be welcomed. As a consequence of such a realist attitude some old metaphysical difficulties about space and time, and about substance and qualities, should disappear. Lastly, it is necessary to abandon the notion that what we call 'values'—truth, beauty and goodness—are ingredients of the world at large. As Alexander has said, "Values are human inventions". This means that, in the sphere of ethics, actions are to be judged by their

consequences, not in terms of any supposed *a priori* moral principles.

These are examples where the philosopher should look to the man of science for guidance; but there are others where the philosopher should be able to help the man of science. For one thing, he can urge the need of caution in accepting the paradoxes that have been prominent in recent scientific thought. An example of this is the tendency to attribute physical properties to space. Strictly, space indicates only an interval between things or processes. If it is really empty, it cannot have physical properties. If any such properties have to be attributed, it should be openly acknowledged not to be empty, as was admitted by the old 'ether' hypothesis. Another example is the tendency to make Heisenberg's Uncertainty Principle an argument for abandoning the notion of causality, on which scientific procedure is based.

The philosopher may also be of use in directing attention to unfilled gaps in scientific theory. One of these is the absence of any explanation of gravitation. In spite of the Theory of Relativity, gravitation is still, as it was in Newton's day, a 'brute fact' unconnected with anything else known about matter. Conceivably the internal structure of the atom may provide the answer. Another, and perhaps a more scandalous, gap in theory is that the great problem of the relation of mind and body remains apparently untouched. Although science itself is a process of thought, science tells us nothing about the nature of thought. A serious mistake has perhaps been made in supposing that perception is necessarily confined to the known functions of the human sense organs. The solution of the problem may possibly come from the science of electro-physiology, which is still only in its infancy.

There are already encouraging signs, Lord Samuel concluded, that science and philosophy are coming closer together. If this union becomes complete, and if the long-standing isolation of religion can also be overcome, it may be possible at last for mankind to possess a unified and harmonious basis for thought and action.

The Expanding Universe

A DISCUSSION on the subject of the Expanding Universe was held on January 27 under the joint auspices of the Physical Society and the Royal Astronomical Society, the chair being taken by the Astronomer Royal. The discussion was opened by Prof. G. Temple and Dr. G. C. McVittie in two papers which gave general surveys of the theory of relativistic cosmology and of the information to be derived from astronomical observations.

The first of these papers dealt especially with the developments in relativistic theories of the large-scale structure of the universe since the publication of Robertson's report in 1933¹. The more important of these developments are the investigations of Milne

and his school into the possibility of solving the cosmological problem by the methods of the special theory of relativity, and the researches of Whittaker and his fellow-workers on the form taken by the astronomical distance functions in general relativity.

A cosmological theory which endeavours to explore world structure by means of terrestrial observations is necessarily speculative, and the relativistic theories rest upon two main hypotheses—the uniformity of space-time and the homogeneity of the nebular distribution. The first of these leads to either the special or the general theory of relativity, according as the uniformity is taken to be 'global' or 'local'. The second hypothesis, first formulated satisfactorily

by Milne, then shows that the space-time is stratified in such a way that the line element may be written in the form

$$ds^2 = dt^2 - e^{2\alpha(t)}((1 - kr^2/R_0^2)dr^2 + r^2d\theta^2 + r^2\sin^2\theta d\phi^2),$$

where the world-lines of nebulae ($r, \theta, \phi = \text{constants}$) are orthogonal to the hyper-surfaces of stratification $S, t = \text{constant}$. The general theory provides an expression for $g(t)$ in terms of the cosmological constant λ , the curvature constant k of the hyper-surfaces S (which may be $+1, 0$, or -1), the radius R_0 of S , and the number α of nebulae per unit volume on some specified S . Prof. Temple concluded by directing attention to the fact that the system of real co-ordinates (t, r, θ, ϕ) covers only that region of space-time actually traversed by the nebulae, and he indicated the possibility that an empty region of space-time might exist outside the system of expanding nebulae—as it actually does in Milne's theory.

Dr. McVittie then gave a critical account of the construction of the semi-empirical equations summarizing the observed relations between the red-shift δ , the apparent photographic magnitude m and the number N_m of nebulae with magnitudes less than m . He pointed out that Hubble's equations depend upon a number of *ad hoc* assumptions which are entirely arbitrary in character and unsupported by the general relativistic theory. In these circumstances, the obvious course is to utilize the relations between observable quantities furnished by the general theory. These alone, however, are insufficient and an additional datum is required, which McVittie finds in the estimate of the average mass of the visible nebulae, $M_0 = 4 \times 10^{44}$ gm. His analysis of the observations leads to the surprising conclusion that $k = -1$, so that the hyper-surfaces S are 'hyperbolic' in character, the radius R_0 lying between 10^3 and 10^4 parsecs. The average density is probably of the order of 10^{-29} gm. cm. $^{-3}$ and the effective temperature of the nebular radiation lies between $5,000^\circ$ and $7,500^\circ$. The cosmical constant λ is expressed by the difference of two numbers of the same order of magnitude, and, owing to the considerable uncertainty in their values, no reliable information is forthcoming concerning the value of λ .

In the subsequent discussion, an important point

was raised by Sir James Jeans, who inquired if the sign of k is sensitive to changes in the estimation of the average nebular mass M . In reply, Dr. McVittie stated that the conclusion $k = -1$ would probably persist even if his estimated value of M_0 were increased by a factor of about 50.

Sir Arthur Eddington stressed the importance of basing cosmological investigations upon a standard of length which would be accepted not only in relativity, but also in quantum theory and in metrology. Since such a standard can only be specified in terms of dimensionless numbers, it would necessarily be a structure with definite quantum numbers or composed of a definite number of atoms, as, for example, 10^8 lattice spaces of calcite. Finally, he stressed that theoretical cosmology is a normal and natural extension of well-known physical principles and deplored the mystery with which this subject is sometimes cloaked.

Prof. W. H. McCrea referred to recent nebular counts by Shapley which appear to indicate that the distribution is not isotropic, and he showed by a very simple argument that Hubble's velocity-distance relation would still remain true in any assigned direction. The Astronomer Royal also referred to the lack of homogeneity revealed in Shapley's observations, and appealed to mathematicians to develop a more general theory capable of dealing with this more complex situation. Dr. McVittie in replying to these comments stated that in his very latest paper Shapley admitted that his former conclusion is rendered uncertain by an error of calibration, but he believes that when the correct calibration is completed, there will still remain some lack of isotropy in the nebular distribution.

Prof. W. Wilson stated that in spite of its simplicity, Milne's cosmological theory suffers from the defect that it does not incorporate detailed gravitational phenomena such as planetary motions. On the other hand, he felt that in the domain of general relativity the early simple theory of de Sitter may be an adequate expression of the facts. Prof. Temple said in reply that the de Sitter universe is in fact the ultimate state of all the continually expanding models proposed by general relativity.

A Congress of Aeronautical Geography

THAT there are relations between geography and aviation was officially acknowledged, so to speak, for the first time in the week of November 28–December 3, when the First Congress of Aeronautical Geography (Premier Congrès de Géographie Aérienne) was held in Paris under the auspices of the French Ministers for Air and National Education. It had been organized by the Union Syndicale des Industries Aéronautiques (not by a geographical body), the vice-president of which, General Duval, acted as chairman, and eminent representatives of French science and aviation served as chairmen of various sessions. Twenty-two papers were read, dealing with the different aspects of aviation so far as they may be of interest to the geographer.

The programme commenced with two meteorological papers, read by Messrs. G. Dedeant and A. Viant, of the French National Meteorological Office, and

an excellent discourse on the international regulation of civil aviation, given by Dr. A. Roper, secretary-general of the International Commission for Aerial Navigation. M. R. Bureau, of the Meteorological Office, discussed the stratosphere, and the well-known pre-War pilot and aeronautical inventor, M. R. Esnault-Pelterie, spoke on interplanetary space. A number of papers dealt with the geographical and economic conditions and the statistical results of commercial aviation in general (M. J. Vivant, sub-director of civil aeronautics in the Air Ministry) and of different long-distance air-lines (Messrs. R. Perret, vice-president of the Association des Géographes Français: line France-Madagascar of Régie Air-Afrique; Prof. J. Martin: lines France-South America and France-Indochina of Cie. Air-France; Prof. J. Weulersse: line London-Capetown of Imperial Airways Ltd.; F. Ruellan, director of studies: line Amsterdam-Batavia

of Koninklijke Luchtvaart Mij.; Prof. E. Denny: line New York-San Francisco of United Air Lines, Inc.). The services which aviation is able to render to geography and allied sciences were discussed by the following: M. A. Carlier, manager of the Société Générale de Photo-Topography (on aerial photography); Prof. P. George (on the role of aviation in the exploration of the polar regions); Father Poidebard (on the exploration of ancient civilizations by aeroplane); Prof. A. Demangeon (on the investigation of agricultural systems from the air); M. F. Blondel, chief mining engineer (how to employ the aeroplane for geological investigations and for prospecting); Prof. E. de Martonne (on the contribution of aviation to morphological studies); M. G. Huismann, director-general of Fine Arts (on the aid of aviation in studying and conserving the architectonic treasures of France). There was also an interesting *causerie*

by the well-known airman, M. P. Codos, on trans-continental and trans-oceanic flights. A number of other papers were of a more technical character.

It is to be regretted that the attendance at the Congress was not large; the date of the meeting had been chosen with regard to the sixteenth International Aeronautical Exhibition held at the Grand Palais des Champs-Élysées, but it is obviously not very convenient for a scientific congress. Though the meeting had been intended to be an international one, the speakers were, without a single exception French, and nearly the same is true of the hearers among whom there were only half a dozen foreigners. It is to be hoped that the next Congress of Aeronautical Geography, which will be held in 1940, again in Paris, may have larger and more international support.

CARL HANNS POLLOG.

The Testing of Electrical Switchgear

THE Department of Scientific and Industrial Research stated last year that at the request of a number of manufacturers of switchgear, it was considering the establishment of a short-circuit testing station at the National Physical Laboratory which would be capable of testing switchgear specified to be able to break a circuit having a current I flowing in it with a possible maximum voltage V across the gap of the circuit breaker, when the product of V and I is 250 million volt-amperes, certain limitations being made as to the value of V and I . The cost of such a laboratory would be very high, as it would have to be built at an appreciable distance from other laboratories and it would have to generate its own power. Only a limited number of full-scale tests could be made per annum and so it would need a large Government grant.

The Department, therefore, issued a questionnaire to interested firms and bodies, inviting their views on various aspects of the proposal and on certain tentative proposals by means of which the National Physical Laboratory might be able to issue certificates that the gear has successfully passed certain specified tests. The replies disclosed a considerable measure of agreement. It was desirable to provide testing facilities which would be available for those manufacturers who did not possess testing stations, and that it should also be possible for such manufacturers to obtain certificates issued by an independent body in respect of such tests. At the same time, those companies which have already erected short-circuit testing stations for their own use indicated some doubt as to whether additional testing capacity in Great Britain was justified as there were already in existence greater testing facilities than are available in any other country in which switchgear is produced. They pointed out that they had spare capacity available. They offered to assist the Department in exploring the proposal further by supplying information from their own experience. As the result of most friendly discussions with the Department, it appeared possible to collaborate with the owners of existing short-circuit testing stations and so provide facilities in those stations for testing for any British manufacturer. Negotiations to this end began in 1937.

Agreement has been recently reached on a scheme which it is hoped will be adequate to meet requirements. This scheme permits the existing testing stations to continue to issue their own certificates and in addition provides facilities for the issue of N.P.L. certificates when required in respect of circuit-breakers coming within the agreed range which attain a standard of performance defined in the appropriate British Standards specification. The negotiations were made much easier by the fact that the owners of existing stations had already taken preliminary steps to co-ordinate their work and had provisionally decided to form an 'Association of Short-Circuit Testing Authorities' which would act as a testing or certifying body. This Association is now being incorporated. The main features of the new scheme are as follows. Owners of testing stations will provide facilities to any British manufacturer without distinction, and will undertake that the full time use of one test bay will be made available collectively, by the existing testing plants, for tests for those manufacturers who do not themselves own testing stations. Tests will be normally carried out to the requirements of a definite British Standards specification. While the Association of Short-Circuit Testing Authorities will issue its own certificates of rating and records of performance, it will be possible to obtain N.P.L. certificates. Application for N.P.L. certificates under the arrangements should be addressed to the Director, National Physical Laboratory who will decide at which station any individual test can be made. Strict confidence will be observed in connexion with the design of circuit-breakers submitted for test.

The stations at present included in the scheme are those of: The English Electric Co., Ltd., the General Electric Co., Ltd., the Switching Testing Co., Ltd. Trafford Park, which is jointly owned by the British Thomson-Houston Co., Ltd., Messrs. Ferguson Pailin, Ltd., and the Metropolitan-Vickers Electric Co., Ltd.; The British Short-Circuit Testing Station Ltd., Hebburn-on-Tyne, owned by Messrs. A. Reyrolle and Co., Ltd. As soon as the National Physical Laboratory is ready to receive orders for test leaflets giving full details of the arrangements for tests including particulars of charges, will be available.

Protective Films on Metals

TWO papers presented at the Autumn Meeting of the Institute of Metals by Drs. L. E. Price and J. J. Thomas dealing respectively with "The Tarnishing of Silver and Silver Alloys and its Prevention" and "Oxidation Resistance in Copper Alloys" may well represent the commencement of a new era in the investigation of alloy systems resistant to oxidation and scaling. It has been suggested by Wagner that for a film to provide marked resistance to further oxidation high electrical resistance, such as is offered by films of the pure oxides of aluminium, beryllium or silicon is required. This hypothesis is abundantly confirmed by the present authors' work.

When, however, alloys of silver or copper are heated in air under normal conditions, such resistant films cannot be produced owing to the fact that both the constituents of the alloy oxidize simultaneously, yielding a coat, the electrical resistance of which is not high. Optimum results can only be expected when films of a suitable pure oxide are formed. The problem, therefore, with which the authors were faced was the production of films of this type, and their solution of the difficulty calls for the highest praise. By an appropriate pre-treatment protective films of alumina have been formed on alloys of silver or copper con-

taining 1 per cent of aluminium, and remarkable resistance to oxidation and tarnishing both at room and at elevated temperatures has been obtained.

Two methods have been developed for the formation of such films of alumina or beryllia; first by a selective oxidation of the aluminium or beryllium in the alloy by heating in hydrogen containing a partial pressure of water vapour of 0.1 mm., or by the cathodic deposition of films of these oxides. Some idea of the magnitude of this research even in its present stage will be gathered from the fact that 70,000 specimens of silver and its alloys have been exposed for periods up to one year in fifteen different locations.

This work is as yet in its experimental stage, and until data are available regarding the mechanical properties of the films, and particularly their resistance to abrasion, it is not easy to visualize the practical possibilities of the process. It is probably true to say, however, that no more serious disservice to such practical application could be done than by inducing the authors prematurely to abandon their present purely scientific treatment of the subject and to devote their attention to the empirical and routine examination of alloys of possible industrial significance.

F. C. T.

Research on Concrete

THE steadily increasing use of concrete in the construction of buildings and roads has given added impulse to the efforts being made to ascertain how its quality may be improved and how it can be used to the best advantage. One of the most important of the factors which influence the properties of this material is the grading of the aggregate and new and valuable light has been thrown on this by the investigations made at the Building Research Station and at the Road Research Laboratory, the results of which have now been published*.

That the strength of concrete depends directly upon the ratio of water to cement and that other factors are of importance mainly in so far as they affect this ratio is now well established. It follows that the grading of the aggregate determines the strength of the concrete inasmuch as it influences the water content required to bring it to the desired degree of workability. The now widely known method of consolidating concrete by vibration may be used to obtain increased strength because it is possible thereby to consolidate a drier mix, thus reducing the necessary water-cement ratio. The term 'workability' has generally been held to convey an impression of the ease or otherwise with which a mix can be placed, but no precise definition has previously been attempted. It is shown here that the only part of the applied work which is usefully employed in the preparation of the mix is that used in overcoming the internal friction of the concrete and the friction between concrete and mould or reinforcement. Of this useful work, the only portion

depending on concrete alone is due to the internal friction and, from this consideration, workability is defined as the property which determines the amount of internal work required to compact the concrete.

For the measurement of this property, the slump test is shown to be defective in two respects, and the compacting factor test, finally chosen as suitable, is based on the above definition and measures the amount of compaction produced by the application of a standard quantity of work. In order to determine the effect of compactness a series of tests was carried out in which the specimens received different amounts of tamping and therefore contained different proportions of air-voids. The loss of strength due to a degree of under-compaction, as measured by the proportion of air-voids, was found to be 30 per cent when the voids were 5 per cent and as much as 90 per cent with 25 per cent of air-voids. It was shown also that, provided the specimens were fully compacted and had the same water-cement ratio, quite large variations of aggregate grading and shape of particles had no appreciable effect on strength. The grading is of importance only in so far as it affects workability and the water-cement ratio necessary to obtain the required workability, and its suitability should be judged in relation to the cement content and the degree of workability required.

The paper fully describes the tests made, and gives photographs in illustration of them, while the quantitative results are adequately set out in tables and curves. From the various data supplied it should be possible for the engineer to obtain the best combination of workability and strength for any particular purpose.

* Department of Scientific and Industrial Research and Ministry of Transport, Road Research, Technical Paper No. 6. "The Grading of Aggregates and Workability of Concrete." (London: H.M. Stationery Office) 1s. 3d.

Science News a Century Ago

Royal Astronomical Society

At the anniversary meeting of the Royal Astronomical Society held on February 8, 1839, the council congratulated the Society on the flourishing conditions of its finances, and on the activity and zeal which were displayed in all branches of astronomical science, marked more especially by the recent discovery of the parallax of the fixed stars, by two of the fellows of the Society in different hemispheres. Obituaries of deceased members were read and mention made of the services they had rendered to science; special reference was made to the late Dr. Bowditch of Boston. The gold medal for the year was awarded to the Hon. John Wrottesley for his catalogue of the right ascension of 1318 stars—a work which had been of great assistance in the formation of the new general catalogue then in course of reduction.

Sir John Wrottesley, afterwards Baron Wrottesley, was born in 1798 and died in 1867. A barrister by profession, he served as president of the Royal Astronomical Society in 1841–43 and as president of the Royal Society in 1854–57.

Nitrogen in Plants

"Some experiments made by Boussingault," said the *Athenaeum* of February 9, 1839, "show that trefoil, cultivated in a soil previously calcined to a red heat, admits a certain quantity of nitrogen into its organisation, which probably proceeds from the atmosphere. On repeating the experiment with peas, a similar result was obtained; and besides this, the peas, with no other nourishment than that which had been derived from water and air, have flowered and yielded perfect seeds, and the nitrogen was more than double in quantity to that originally contained in the peas. On comparing these experiments with those made on oats, etc., it appears that only certain plants are apt to derive nitrogen from the air, but the manner in which this elementary body fixes itself in vegetables is not known."

University Events

LONDON.—Dr. John McMichael has been appointed to the University readership in medicine tenable at the British Postgraduate Medical School. He will take up his duties early in March. Since 1936 he has been Johnston and Lawrence research fellow of the Royal Society of Edinburgh and extra honorary assistant physician at the Royal Infirmary, Edinburgh.

Dr. W. T. J. Morgan has been appointed as from January 1, 1939, to the University readership in biochemistry tenable at the Lister Institute of Preventive Medicine. Since 1929 he has been biochemist and first assistant in the Serum Department of the Institute at Elstree.

The title of professor emeritus of mycology in the University has been conferred on Prof. E. S. Salmon, formerly University professor of mycology at the South-Eastern Agricultural College.

Mr. C. C. L. Gregory, lecturer in astronomy at University College, has been appointed director of the University Observatory.

Societies and Academies

Paris

Academy of Sciences (*C.R.*, 208, 57–131, Jan. 9, 1939)

A. LAGROIX: Silent stages in the formation of a new crater of the caldera type at the summit of the Piton de la Fournaise (Reunion Isle).

E. ESCALANON: Definition of force in the special theory of relativity.

B. STIEGLITZ: A fundamental theorem of geometry on algebraic surfaces.

S. EILENBERG: Co-homologies and continuous transformations.

R. SALEM: Mean convergence of Fourier series.

L. KANTOROVICH and A. PINKUS: General forms of partially additive functions in certain semi-ordered spaces.

N. OBRUCHKOFF: Zeros of some *fonctions entières*.

C.-T. CHUANG: Holomorphic functions in the *cercle unité*.

E. LEFEBVRE: Functions of a complex variable defined by a linear relation between the variable and logarithm of the function, the coefficients being some polynomials related to the function.

O. YADOFF: A method of measuring the speed of the 'front' of a gaseous jet.

O. SALOMANU: The velocity of sound in binary mixtures of liquids, by a resonance method.

T. V. IONTSOU: Mode of action of ionized gas oscillators in the magnetic field.

MM. Z. SOUBARW-CHATELAIN: Application of the conductimetric method to the simultaneous determination of molybdic acid and of ammonia in the ammonio-molybdates.

G. CHAUDRON and A. MICHEL: Thermo-magnetic characteristics of cubic iron sesqui-oxide.

L. DUNOYER: Emission from the ends of luminous tubes: numerical results.

G. DÉCHÈNE: A new type of photo-electric cell. The contact resistance of a semi-conducting piece or treated 'Cellophane' applied to a layer 2–3 mm. thick of yellow or red mercuric oxide can be used for qualitative work in the visible and ultra-violet.

Mlle. M. PERRY: Element 87, a derivative of actinium. There would appear to be two isotopes of atomic number 87, one of short life (21 min.) announced here, and another of long life found by M. Hulubei.

B. PONTECORVO and A. LAZARD: Nuclear isomerism produced by a continuous spectrum of X-rays.

G. OCHIALINI: Measurement of the effect of latitude on cosmic ray showers. Measurements at sea between Bahia and Trieste suggest that the showers are due to radiation of the same quality in both equatorial and temperate regions.

R. DELAPLACE and C. BÉCHARD: Determination of freezing point and boiling point, at reduced pressure, of mixtures of ethylglycol and water.

P. BASTIN: Researches on the evolution in air in water and in a vacuum, of brittleness due to acid pickle in extra-soft annealed steel.

P. CARRÉ and L. PRIGNÉ: Some anti-oxygen effects from the point of view of the practical rule of the 'electronic strain'.

L. PALFRAY and S. SABBATAY: Catalytic dehydrogenation, by means of Raney or ordinary nickel.

J.-H. HOFFET: Genesis of iron beds on the right bank of the Red River (Tonkin). There is a large reserve of iron capable of exploitation.

C. DAUXÈRE: Geographical distribution of lightning strokes in the Département du Gers.

MILLÉ, M. CHLÉN: New preliminary researches on the synapses of red algae.

R. GAUTHERET: Possibility of realizing indefinite culture of tissues of carrot tubercules. Such tissue has been maintained for more than a year, and is very resistant to changes of conditions.

M. AUBERTOT: Presence of a dorsal contractile vessel in the genus *Acerentomon*.

P. CHABANAUD: Geonemy of unsymmetrical eleutherozoans.

P. CHAUCHARD: Chronaximetric analysis of the block of conduction in nerves; realization of a analysing heterochronism.

A. POLACK: Correcting glasses for those operated on for cataract.

P. LÉPINE and P. SÉDALLIAN: Presence of poliomyelitic virus in the intestinal contents of a living infant in an infected family; isolation of the virus.

Amsterdam

Royal Netherlands Academy (Proc., 41, No. 9, 1938).

L. RUTTEN: Geological investigations in mid-Dalmatia and Herzegovina.

J. G. VAN DER CORPUT: Hyperconvex aggregates in the plane.

T. L. DE BRUIN and J. N. LIME: Absorption spectrum of thorium.

B. J. D. MEUSE: Some observations on special structures in the cell walls of plants.

J. VAN SOEST: Tilted late breccias on the southwestern Biokovo slopes (Dalmatia).

F. DE WITT PUYT: The Klobuk (a mountain) at Ljubuški, a tectonic klippe.

D. G. MONTAGNE: Some Rudistæ and Nerineidæ from mid-Dalmatia.

F. KUIJER: Middle Eocene Foraminifera from the lyach in the neighbourhood of Omiš, Dalmatia.

A. TEN DAM: Foraminifera from the Oligocene and Miocene of the Eastern Netherlands.

M. J. L. DOIS and B. C. P. JANSSEN: Studies on phosphorus metabolism in normal and rachitic rats with a radioactive phosphorus isotope (2). The total phosphorus and lipid phosphorus content and the formation of lipid phosphorus.

E. FREY: Studies on the hypothalamic optical nerve of the Amphibia (1). *Rana mugiens*, *Rana esculenta*, *Bombinator pachypus* and *Pipa pipa*. (2) *Proteus anguinus* and the phylogenetic significance of the hypothalamic optical nerve.

A. MOCHTAR and W. K. MEERTENS: Single cell culture of *Leptospira*.

Brussels

Royal Academy (Bull. Classe Sci., No. 11, 1938).

C. J. DE LA VALLÉE POUSSIN: Irregular points. The determination of masses by potentials (2).

P. BURNIAT: Note on certain varieties of Segre.

L. LINSMAN: Certain topological evolutions.

L. DEBRUIDT: Fundamental surfaces of the second kind of the birational transformations of four-dimensional space.

J. THORAU and J. VERHULST: Atacamite from Katanga. Crystallographic, optical and X-ray investigations on this mineral.

J. PASTERELS: Sensitizers and an organizer in the activation of the egg of *Barnes candida*.

J. BRANDIS: Effects of the local application of ultra-violet rays on the blastula and gastrula in the *Discoglossa*.

Copenhagen

Royal Danish Academy of Sciences and Letters, October 21.

NIELS BOHR: Reactions of atomic nuclei. In connexion with the communication of a paper, written in collaboration with G. Placzek and R. Peierls, a general survey is given of the use of simple mechanical ideas and thermodynamic analogies to explain several characteristic features of nuclear reactions.

November 4.

FRIEZ BUCHTAL and J. LINDHARD: Physiology of the striated muscle fibre. On the basis of the experimental results from work on isolated cross-striated muscle-fibres, a new contraction hypothesis is put forward. The anisotropic segments of the myofibrils consisting of myosin-chains are more or less stretched in an electrostatic field in the resting fibre. On excitation, this electric field decreases, the myosin micellæ become coiled up, whereby the fibre contracts.

November 18.

J. N. BRONSTED: Foundation and formulation of the thermodynamic laws. On the basis of points of view previously stated concerning the impossibility of heat-work transformation in ordinary thermodynamics, the fundamental conceptions and principles in thermodynamics are developed in a form which to some extent deviates from the traditional treatment of the subject.

December 2.

OTTO NEUGEBAUER: An edition of an Egyptian astronomical papyrus (Pap. Carlsberg 9) prepared in collaboration with A. Volten. The papyrus contains a calculation of new moons and for the first time gives some insight into a mathematical astronomy among the Egyptians. [See also NATURE of January 21, p. 115.]

December 16.

C. M. STERNBERG: An examination of the Skrydstrup woman's hair and the material of her dress.

Vienna

Academy of Sciences, December 7.

H. HABERLANDT: Radiobarytes from Teplitz and Karlsbad. It is found that the radioactive material is concentrated on the surface of the barytes crystals, and in particular along cracks. The fluorescence spectrum of the barytes from Teplitz indicates that the radioactive material is uranium, while the Karlsbad mineral contains no uranium and probably owes its activity to radium.

F. WERNER: Report of eight scientific expeditions to Greece.

S. BLATTMANN: Stratigraphy and tectonics of the Radstädter Tauern.

Forthcoming Events

[Meetings marked with an asterisk are open to the public.]

Monday, February 6

UNIVERSITY COLLEGE, LONDON, at 5.—Prof. J. H. Burn: "The Action of Drugs in Muscular Fatigue and as Circulatory Restoratives" (succeeding lecture on February 8).*

UNIVERSITY COLLEGE, LONDON, at 5.30.—Prof. H. S. W. Massey: "Quantum Statics" (succeeding lectures on February 20, March 6, 17 and 20).*

BIRCKBECK COLLEGE PHYSICAL SOCIETY, at 6.—Prof. G. I. Finch, F.R.S.: "Structure of Work Surfaces".*

Wednesday, February 8

UNIVERSITY COLLEGE, LONDON, at 7.30.—Dr. E. C. Willatts: "The Use of Land in Planning the London Region".*

ROYAL SOCIETY OF ARTS, at 8.15.—R. Kronfeld: "Gliding and Soaring".

Thursday, February 9

BEDFORD COLLEGE FOR WOMEN (in collaboration with the SOCIETY FOR THE PROTECTION OF SCIENCE AND LEARNING), at 5.15.—Prof. Gilbert Murray: "Why should Science and Learning be Protected?"*

CHEMICAL AND PHYSIOLOGICAL SOCIETIES, at 5.30.—Discussion on "The Use of Isotopes in Biology", to be opened by Prof. G. von Hevesy.

Friday, February 10

ROYAL INSTITUTION, at 9.—Prof. Max Born: "Cause, Purpose and Economy in Natural Laws".

Appointments Vacant

APPOINTMENTS are invited for the following appointments, on or before the dates mentioned:

SCIENTIFIC OFFICER in the Air Ministry Scientific Research Pool—The Chief Superintendent, Royal Aircraft Establishment, South Farnborough, Hants (Ref. No. 301 O. February 17).

ASSISTANT LECTURER IN ZOOLOGY in University College, Exeter—The Registrar (February 20).

PROFESSOR OF VETERINARY SCIENCE and PROFESSOR OF ANATOMY in the University of Sydney—The Universities Bureau of the British Empire, 88a Gower Street, London, W.C.1.

Agricultural Research and Education

THERE can be few to-day who would deny that scientific research lies at the base of material progress. Ninety years ago or more, the Prince Consort recognized the fact ; but it was not until the middle of the Great War that the Government in Great Britain first embarked upon a comprehensive scheme of State assistance for industrial and scientific research. Agriculture was a little more fortunate, because, thanks to the perspicacity of Mr. Lloyd George, a Development Fund was established in 1910-11 which, among other objects, was designed to aid and develop agriculture and rural industries. Since that time, an increasing amount of money has been given to promote and maintain agricultural research, and in the year 1938 the State spent at least £700,000 on this object in Great Britain. This sum represents about 90 per cent of the total expenditure on agricultural research and advisory services, to which farmers themselves contribute very little, and is distributed among some fifty institutions, of which twenty-eight are devoted solely or primarily to research.

The chief recipients of grants are agricultural colleges and university departments of agriculture, which also have educational functions ; State institutions, like the Veterinary Laboratory at Weybridge, Surrey ; and private institutions, like Rothamsted, the Rowett Institute, and the Royal Veterinary College, London. There are 673 research workers at the chief institutions and the total number in Great Britain is rather less than one thousand. Propagation of the results of research, and general advisory work, are delegated to seventeen principal advisory officers located in sixteen provincial advisory centres which are usually university departments or agricultural colleges, and lower down the scale are advisory officers and

agricultural organizers appointed by agricultural education committees of county councils. The councils make small grants for research to university departments, agricultural colleges and research institutes. Research is also conducted by private interests like Imperial Chemical Industries Ltd. at Jealott's Hill, and the Welloome Physiological Laboratories at Beckenham, Kent. Lastly, there are nine Imperial bureaux and two Imperial institutes which collect and collate information and abstract the scientific literature for research workers throughout the Empire.

The above and many more interesting and relevant facts are set out in an admirable report published by PEP*, which records the findings of a special committee it appointed to examine the adequacy of the provision made for agricultural research in Great Britain, how it is administered, and to what extent the measures taken to get farmers to utilize the results have been successful. The report sees much to commend in the provisions made for agricultural research, but it is also critical, and in the interests of progress, our remarks will be confined in the main to two objects of criticism : the cumbersome machinery of administration and finance, and the failure to 'put over' the results of research to working farmers.

Responsibility for the administration and finance of agricultural research in Great Britain is divided among numerous authorities of the central Government : the Agricultural Research Council, the Development Commission, the Ministry of Agriculture for England and Wales, the Department

* Report on Agricultural Research in Great Britain : a Survey of its Scope, Administrative Structure and Finance, and of the Methods of making its Results known to Farmers, with Proposals for Future Development. Pp. vi+146. (London : PEP 1938.) 8s. 6d. net.

of Agriculture for Scotland, the Dominions Office (for the Imperial institutes and bureaux), the Privy Council, and the Treasury. This multiplicity of authorities has many drawbacks, and PEP advises that the Development Commission, which has already lost some of its initial functions, should be abolished as a piece of "superfluous stage property". Many will think that the pruning process might be extended, but excessive devotion to old forms and traditions, and a propensity to compromise, seem to be a characteristic of the governmental mind in Great Britain. Government departments are, of course, always fair game for carping critics, but more than one Government inquiry in recent years has recommended the application of the axe.

The organization of agricultural research institutes is criticized by PEP in so far as it is based too largely upon departmental science: more husbandry institutes are wanted, each of which would specialize in a particular crop or product rather than upon a particular science. The low salaries paid to research workers are deprecated, and the creation of a central agricultural research fund, with larger contributions from the industry, is advocated.

The most serious criticism against the existing order is failure to get the results of research translated into farming practice, a failure which, in our opinion, cannot be ascribed entirely to the agricultural education authorities or to the systems under which they work. Agricultural education in England is under three administrations: the Ministry of Agriculture, the Board of Education, and the county councils. From the agricultural colleges and university departments some 2,000 students pass out every year, but surprisingly few of them take up farming on their own account, either because they lack the necessary capital, or because no managerial posts are open to them; most of them take up teaching, or go into administrative service, or join the larger commercial firms.

Agricultural education for the rank and file is administered by the county councils, each of which commands the services of a county agricultural organizer, district organizers, and special instructors. The staffing varies greatly between county and county, and in general the number of instructors appears to be inadequate. Of the 22,000 students who come under the county councils, about half receive their instruction in evening classes only. In addition to itinerant

teaching, the county staffs undertake demonstrations and advisory work. Education is also provided, mostly during the winter months, by the residential farm institutes, in which the teaching is essentially practical. Technical instruction is given in senior schools and in instruction classes financed by the county education committees and the Board of Education. The Young Farmers' Clubs also have educational functions; and lastly, the farming community can gather knowledge and advice from broadcast 'talks', from departmental publications designed to popularize recent advances in technique, and from the agricultural press.

With this medley of administrative organs and public and private agencies, it is small wonder that results have proved disappointing. Agricultural education, like many other institutions of the civilized world, has become far too complex, and only the surgeon's knife followed by Occam's razor can bring us back to simplicity and efficiency. PEP proposes that the county advisory services be transferred to the provincial advisory centres, but other critics would have all the agricultural educational functions of the county councils so transferred. Many would like to see a great extension of the farm institutes, which have accommodation for only a fraction of the youth destined for the land, and their utilization for short courses of instruction for skilled specialized workers.

But perhaps the greatest handicap to the spread of new scientific knowledge is the character of the farmers themselves. Farmers of the old type—they are still in a large majority—who have inherited the prejudices as well as the consummate skill of their forbears usually shy at the sight of the scientific adviser, a reaction that may be partly due to unhappy experience of projects they were induced to adopt by well-meaning but unpractical enthusiasts. On the other hand, there is arising a new generation of farmers, more appreciative and keen, who, if less skilled than their fathers in the old methods applicable to bygone conditions, are open to new ideas and thoroughly progressive in outlook. The day of the old practical farmer is passing—of the man who could himself efficiently perform all the manual tasks of the farm. He was, in essence, a farm labourer with capital. Unless we are to perpetuate peasant farming, it is as unreasonable to expect the modern, and especially the future, farmer to be an expert in the everyday jobs of the farm, as it

is now to insist on the manager of an engineering works being able to undertake all the tasks in his workshop.

As the P E P report indicates, the main hope for the future lies in reformed education in the primary and secondary schools, rather than in the higher seats of learning. Agricultural research is far ahead of agricultural education. Vocational instruction is not wanted in primary schools. The claims of English, arithmetic, geography and an outline of world history must be recognized, but more scope is required for what is termed 'general science', the teaching of broad outlines largely through applications. The pupil who is destined for the land should, we suggest, leave school at fourteen to fifteen years of age, and

serve an apprenticeship lasting one to two years on an up-to-date farm, where he would be encouraged to relate his school science to the facts of farming. He should then return to school, continue his general education, and pursue a more specialized course of instruction in those sciences that bear directly upon agriculture. So trained, it is difficult to conceive of any youth, other than a 'throw-back', entering agriculture without an informed mind and a progressive outlook. Besides instilling knowledge and training the mind to think, education for agriculture, or for any other pursuit, can only be worthy of the name if it inculcates such essential social virtues as willingness to co-operate and consideration for others.

State Control of Private Forests

Forestry and State Control

By Prof. R. S. Troup. Pp. vii + 88. (Oxford: Clarendon Press; London: Oxford University Press, 1938.) 3s. 6d. net.

THE condition of private woodlands in Britain has been the subject of increasing concern ever since the British people began to realize that their former complacent reliance on continuous supplies of timber from abroad is not so well founded as they supposed. The main part of the task of building up a reserve of softwood timber in the country for use in times of emergency has been entrusted to the Forestry Commissioners, but in assigning them their share in this work, it was assumed that through their encouragement and example private woodlands, both hardwood and softwood, would be restored to their pre-War area and their productivity improved. Unfortunately, it has become evident that this assumption was not justified and, as questions of national defence, economic self-sufficiency and political interferences with the flow of trade and commerce seem to be increasing rather than diminishing in importance, it is not surprising if the advisability of taking more intensive measures in regard to private forestry has come to the fore.

The whole tradition of Britain has been against State interference with private productive enterprise, and State action as regards private forestry up to the present has been confined to attempts to induce the private owner to practise more and better forestry by propaganda, provision of

technical education and advice, taxation concessions, planting subsidies and assisted marketing. In many countries, however, the action of the State goes far beyond such measures as these, and may extend to legal restrictions on felling, and insistence on the regeneration of felled areas, employment of certain sylvicultural systems, etc. The degree of control exercised may extend from mere inspection of the forests, to see that the law is not evaded, to the actual management of private woodlands by State forest officers.

In this book, Prof. R. S. Troup gives an account of the methods of control over private forests practised in the chief European countries, and discusses, in the light of knowledge gained by personal visits and inquiries, the actual working of these measures and the attitude of private owners to control by the State. The first half of the work is devoted to a general account of the nature and ownership of forests and a discussion of the question of whether, and in what circumstances, State control of private forests is justified.

After a review of the position of British forestry, the author expresses the opinion that, besides the incidence of death duties and the economic forces acting against forestry in Britain, the main cause of the poor productivity of private woodlands is the absence of adequate technical knowledge on the part of those responsible for their management. The remedy for inefficient management is the employment of properly trained forest managers, but most woodland estates are too small to justify

the appointment of a whole-time manager; the difficulty might be got over by a scheme of co-operation by which a number of estates would be placed under the charge of a single manager. Subsidies would be better devoted towards improving silviculture and forest management (including planting) than towards encouraging planting alone. The author finds it difficult to see how any permanent improvement in private forestry in Britain is possible without some form of compulsion and State supervision, in return for which it may be necessary to offer further concessions and assistance to landowners. "Legislation directed towards imposing State control, should aim at preventing, rather than encouraging the break up of estates; it should avoid penalizing well managed estates, but should aim rather at bringing others into line with them."

As Prof. Troup remarks, it must be admitted that the question of reforming private forestry in Britain is one in which it is easier to indicate the ideal to be attained than to devise workable measures for carrying it out. If the time should come when it is adjudged necessary to formulate legislation for the purpose, the information as to the methods adopted and experience gained in other countries, set out in the second part of this book, should be of the utmost value. These measures naturally vary greatly from country to country, according to geographical situation, social and economic conditions and past history. Perhaps the most interesting to us are the forest

laws of Denmark, which approaches most nearly to Britain in the smallness of its forests and the nature of its government. Most of the woodlands of Denmark are 'reserved forests', and they must be maintained under a high forest crop, the proportion of hardwoods must not be diminished, fellings must be succeeded immediately by afforestation and the crops managed under approved silvicultural principles. Inspection by State forest officers ensures the carrying out of these provisions. Speculation in woodlands is checked by a law that, after a sale of reserved forest, the purchaser, for a period of ten years, can only make fellings necessary for the domestic use of the estate or for the proper management of the woods (sustained yield). On the other hand, reserved forests are subjected to lower land taxes, and State assistance is given by providing technical advice.

Though control in Denmark is strict, there are remarkably few complaints from landowners, and this appears also to be generally the case elsewhere. The limitation of the freedom of the owner is compensated by the benefit he obtains financially from properly managed woodlands and his sense of security that his forests will not be devastated by his successors in title.

Prof. Troup has succeeded in presenting in a limited space a great deal of information which has hitherto not been easy of access and will be welcomed, not only by students of forestry but also by a wider public.

T. T.

Karl Pearson

Karl Pearson:

an Appreciation of some Aspects of his Life and Work. By E. S. Pearson. Pp. viii+170+9 plates. (Cambridge: At the University Press, 1938.) 10s. 6d. net.

THIS handsome volume is a reprint of two articles recently published in *Biometrika* (vols. 28 and 29), with the addition of a couple of extra appendixes giving respectively the full syllabuses of Karl Pearson's Gresham College lectures on statistics during 1891-94, and notes of his lecture-courses on that subject at University College, London, in 1894-95 and 1895-96. The author asks "that wider audience" to which the memoir is now made available to bear in mind that it is "in no sense a Life" of his father. That seems to be going a little too far. In so far as a man's labours are his life—and for Karl Pearson they

were that to a greater extent than for most men—this is an admirable Life: brief certainly, with plenty of room for filling in details, but well-ordered, and very readable at all events by the statistician, to whom it is mainly addressed, much being inevitably more or less technical. But there is more in it than this. Portraits, letters, lighter sketches of life on vacation or in the laboratory, and friendships, serve to fill in the human side of the picture.

Prof. Pearson divides the life into nine periods into which it naturally seems to fall. 'K.P.' was born in 1857. The early years of school and university carry us to 1879, and there is a delightful portrait (Plate II) of the schoolboy Karl. Then came the wander-years, 1879-84, the years in Germany, the years of historical research and of many lectures afterwards collected in the "Ethic of Freethought"; the years of "The New Werther"—

a most interesting revelation this, 'K.P.'s' first published work and a striving after a creed of life; and of "The Trinity: a Nineteenth Century Passion Play". This period closed with his election to the chair of applied mathematics and mechanics at University College, London, in June, 1884, at the early age of twenty-seven years. The first years of his occupation of the chair, from 1884 until 1890, apart from the heavy work of preparing and delivering his over-numerous lectures and supervising the drawing-classes in connexion with them, must have been largely dominated by the "History of the Theory of Elasticity" and "The Elastical Researches of Barré de Saint-Venant"; but the period covers also some of the later lectures of the "Ethio".

Then came the publication of Galton's "Natural Inheritance" in 1889 and the appointment of Weldon to the chair of zoology at University College in 1890, and 'K.P.'s' main energies were step by step diverted into the channel in which they were to flow for the remainder of his life, though it was still to be some twenty years before all the labour of the lectures to engineers and B.Sc. students could be dropped. They were years of incredible activity. In 1892 came the "Grammar of Science", in 1893 vol. 2 of the "History of the Theory of Elasticity". Then, during the same years, there were the Gresham Lectures, and from 1893 onwards the succession of fundamental memoirs in the *Proceedings* and the *Transactions of the Royal Society* in which the foundations of modern statistical methods were laid. In 1900 came the rediscovery of Mendelism, and the unfortunate controversy that followed in connexion with the Evolution Committee of the Royal Society. In 1901 *Biometrika* was started, and there followed several years in which much active work was done in the collection of data relating to inheritance.

The tragic death of Weldon in 1906 brought this period to a sudden end, and, as the author says, seems to have made a definite dividing line in his father's life: thereafter there was less biology and more theory of statistics, more miscellaneous papers, in his output. Galton's death in 1911 made another break. By the foundation of the Galton professorship of eugenics, 'K.P.' was at long last, after twenty-seven years' tenure of the post, enabled to resign the chair of applied mathematics, and the diversion of energies it had entailed came to an end. But not for long was he to have leisure and opportunity for developing the new department and celebrating its founder in the magnificent "Life, Letters and Labours". War came in 1914, and with the war the diversion of all available staff to war-work: the strain, heavy enough in itself, was made the heavier by

inevitable anxiety as to the future. Revivification, however, came rapidly with peace. Funds to meet the enormous rise in building costs were obtained from one source and another, the new laboratory arose, and the years from 1920 until his retirement in 1933 saw a steady output of work and an activity that is truly amazing when 'K.P.'s' age is recalled. Retirement left but a brief space, still spent in activity, before death came with merciful suddenness in the spring of 1936.

There was no one like 'K.P.' in his generation. To find his like I think one must go back to the seventeenth century: in many respects—in his outstanding ability, his width of knowledge and interests, his energy, his complete self-confidence, his 'trespassing' into divers fields, and his continual immersion in controversy from early manhood almost to the grave—John Wallis not a little resembled 'K.P.'.

Prof. Pearson has well acquitted himself of the task within the limits he set. In each period the work that mainly dominated it is clearly set out and the principal memoirs discussed. In particular his treatment of controversies, which must often have been difficult, is highly to be commended for its balance and restraint. Here I would like to make one comment, thinking less of the past than of the present and the future. "Writers rarely . . . understand," wrote 'K.P.' in 1914 (p. 66), "the almost religious hatred which arises in the true man of science when he sees error propagated in high places." Surely neither in the best type of religion nor in the best type of science should *hatred* enter in at all. One may appeal to the earlier 'K.P.' who wrote of the freethinker ("Ethio", p. 22), "he has no right to abuse, he can only endeavour to teach". In one respect only has scientific controversy perforce improved since the seventeenth century. If *A* disagrees with *B*'s arguments, dislikes his personality and is annoyed by the cock of his hat, he can no longer, failing all else, resort to abuse of *B*'s latinity, cf. Hobbes *v.* Wallis.

To those of us who knew the living man, such a memoir as this shows us some aspects of him that we could not have known or did not know, and other aspects, that we did know, seen by another eye from another point of view. We are grateful for Prof. Pearson's work. But there is a younger generation who scarcely knew him, or did not know him at all, to whom he is only the shadow of a name, to whom even his work is known only at second hand or at third, seen through the distorting medium of text-books. It is to be hoped that this younger generation of statisticians will read and digest the memoir, and make use of the select bibliography it contains. It will do

much to enable them to visualize the man who founded modern methods in statistics and will, it is to be hoped, send them back from text-book statements to the original sources. Let it be added that the price is very low for so handsome a

volume with its wealth of portraits—though there isn't one of the Karl who returned from one summer vacation (somewhere about 1888, I think) to startle his class with the possession of a beard like a Viking.
G. UDRY YULE.

Protein Chemistry

Chemistry of the Proteins

By Dr. Dorothy Jordan Lloyd and Agnes Shore. Second edition. Pp. xi+532. (London: J. and A. Churchill, Ltd., 1938.) 21s.

DURING the twelve years which have elapsed since the publication of the first edition of this book, the constitution, structure and properties of the proteins have been studied by an ever-increasing number of workers, employing every available method of experiment. Fundamental and far-reaching advances in knowledge have been made, and the volume under review, which includes references to most of the papers published up to the end of 1936, as well as a few in later years, is considerably larger than the first edition.

The general plan of the original book has been retained, except that two minor chapters, dealing with the industrial uses of the proteins, have been omitted, and a few of the remaining chapters rearranged. In the preface to the second edition, the authors express regret at having had to omit references to the industrial aspects of protein chemistry, but the decision was certainly wise, because adequate treatment would demand a separate volume for each industry, and some such volumes are now available. On the other hand, the co-ordinating effect of recent advances in knowledge is such that the point of subdivision of the book into two parts is both artificial and unnecessary.

The new volume, like the old, commences with a survey of the nature and properties of the amino acids. This is followed by an outline of the biological classification of the proteins in a chapter which reflects both the former empiricism of the subject and the clarification which has resulted from recent research. Besides being greatly enlarged, the succeeding summary of available methods of protein analysis is a model of lucidity, as is the account of the methods used for establishing the homogeneity and identity of the proteins. The relationships between constitution and nutritional value are discussed in a section which includes an excellent summary of the work

of Rose and his collaborators, and the obscurity which has cloaked the subject of indispensable amino acids seems now to be disappearing.

A brief but interesting survey of the nature and classification of the enzymes, including a summary of Bergmann's work with simple peptides, forms an excellent introduction to the consideration of molecular size, structure and shape. It is here that the influence of recent research is most strongly felt, and due consideration is given by the authors to the results of X-ray and ultracentrifuge methods of experiment, as well as the more theoretical treatment of Wrinn and Bergmann. The manner in which these several methods of reasoning and experiment concur in revealing an ordered arrangement of amino acids in the protein molecule, and in fixing its size, is so striking that little regret need be felt that the authors were unable to emphasize the general agreement by considering the subjects of osmotic pressure and protein films in the same chapter. In the remainder of the book, the structure of the protein molecule, so far as it is known, is made the basis of a discussion of combination with acids and alkalis, the related phenomena of osmotic pressure and swelling, denaturation, and the theory of protein solutions. As regards the concluding chapter, which contains a number of misprints, it is difficult to avoid the conclusion that the authors might have increased the cogency of their argument by including the subject-matter in appropriate earlier sections of the book.

Besides being a lucid and concise survey of the present state of protein chemistry, the volume includes exhaustive lists of references, and there can be no doubt that it will be even more welcome than its predecessor. The authors' treatment of the subject is sufficiently, but not unduly, coloured by their own views to make interesting and provocative reading, and, in the words of Sir Frederick Gowland Hopkins's introduction, "even the specialist . . . may well find as the result of reading this book that the fertile mating of facts, which for him were previously disconnected, has yielded him a progeny of happy suggestion for research".
J. B. SPRAKMAN.

Academic Psychical Research

(1) Science and Psychical Phenomena

By G. N. M. Tyrrell. Pp. xv+379. (London: Methuen and Co., Ltd., 1938.) 12s. 6d. net.

(2) Psychical Experiences

Evidence of Purpose. By Zos Richmond. Pp. viii+112. Foreknowledge. By H. F. Saltmarsh. Pp. viii+120. Ghosts and Apparitions. By W. H. Salter. Pp. vii+138. Hypnosis: Its Meaning and Practice. By Eric Cuddon. Pp. viii+169. 3s. 6d. net each. (London: G. Bell and Sons, Ltd., 1938.)

TO the impartial and independent observer, the relations between psychical research and spiritualism are always of interest. The one can scarcely be active without the other: co-operation is often urged and as often rejected; and a kind of armed neutrality is the result. The more earnest psychical researchers are perfectly well aware that as long as they support and treat with consideration the large number of dubious mediums who prey upon the credulous, their own claims to serious attention are put in jeopardy; whilst the spiritualists demand from them something more than passive inaction as the price for the privilege of investigating the more promising cases.

In the last ten years, a gradual separation has been taking place, for the psychical researchers have now become fully aware that the scientific citadel is not to be stormed by the motley crowd, which has for so long formed a part of their supporters. Not only the method of approach but also the subject matter itself has had to undergo revision. For the time being, the scientific world is not to be presented with accounts of floating tables and phantoms looking as if they were made of chewed paper. It is hoped that better success will be achieved by statistical formulæ and philosophical disquisition. An illustration of these tendencies can be seen in the five volumes now under review.

(1) Mr. Tyrrell, in his summary of a good deal of the field included under the term 'psychical research', has given us one of the best surveys so far published. No one who reads this persuasive and thought-provoking volume can fail to be impressed by the author's obvious sincerity and enthusiasm; neither can he fail to conclude that if this be psychical research, then it is indeed strange that the scientific world remains so aloof and seemingly unfriendly. For here he will find, set out in orderly sequence, accounts of the principal mental phenomena, graded under such terms

as telepathy, clairvoyance, precognition and retro-cognition. After past work is viewed from its historical aspect, the more recent cases, both spontaneous and experimental, are examined and criticized. In the latter part of the book the philosophical and psychological implications are described; and the problem of the nature of human personality is considered in its relation to the phenomena which have been discussed.

(2) If Mr. Tyrrell's book be regarded as an admirable text-book for study, then the other volumes, the titles of which are noted above, can be used as supplements, containing as they do additional cases and discussions. This new series is really a highly condensed selection of material published for the most part in the *Proceedings* and *Journal of the Society for Psychical Research*. Thus the student who wishes to become acquainted with the best cases the Society has to offer cannot do better than read these books, and then, if he wishes, he can go back to the original sources for additional information.

It can scarcely be denied that, viewed as attempts to claim scientific recognition, these volumes are of great interest. To one wholly untrained in psychical research and with no knowledge of what lies behind much of the impressive façade, the effect must be considerable. Only careful analysis and years of experience will weaken that effect, for it is but here and there that the authors under review cite cases as good, which are so clearly full of flaws that suspicion of their critical faculties is aroused. Moreover, the difficulty of appraisal is increased when it is remembered how hard it is to obtain repetitions under varying conditions, and how disinclined experimenters in this field generally are to permit critical and well-informed persons to test their results and examine their evidence.

This does not by any means imply that the value of the evidence here so carefully collected is worthless. But it does suggest that extreme care should be exercised before accepting fully the claims made by these writers and by others like them. Psychologists would do well to remember that these obscure problems belong properly to their own studies; and a neglect of them merely indicates a wish to remain in ignorance of some of the more important aspects of human mental activity. To them, therefore, these volumes can be heartily recommended as text-books, which illustrate better than most what serious psychical research is and what its exponents are doing.

The Kandy Flora

By A. H. G. Alston. Pp. xvii+109+101 plates. (Colombo: Government Record Office, 1938.) 3.50 rupees.

THIS is the first of four local Floras proposed for the island of Ceylon. It was actually ready in 1928, but financial stringency dictated its being withheld until 1938. The area comprised is "all the country within easy walking distance of Kandy" at an average elevation of 1500 ft.

Naturalized aliens as well as all known native phanerogams are briefly described, with the exception of the representatives of the Eriocaulonaceae, Cyperaceae, and Gramineae which, together with the cryptogams, are merely listed in an appendix. The commonly cultivated plants are mentioned without description. Short descriptions of the 98 families (101 including the three mentioned above) and the genera are given. There is a handy artificial key to the families, which, so far as the Dicotyledons are concerned, are arranged according to the phylogenetic scheme of Dr. J. Hutchinson. The sequence for the Monocotyledons is that of the "Pflanzenfamilien". Generic keys are provided for each family with more than one genus, and for each genus represented by more than one species. Altogether 501 species of flowering plants (excluding the cultivated) are included, and 299 cryptogams are listed. Vernacular names are cited for most of the species. A glossary of botanical terms and a comprehensive index are provided. Finally, 404 of the species of phanerogams are illustrated by good, if rather small, drawings, mostly accompanied by enlargements of floral or other distinctive features.

As is to be expected from the author of the supplementary volume to Trimen's "Handbook of the Flora of Ceylon", the nomenclature is up to date, at least for 1928. The printing is good and the general 'get up' quite satisfactory, but the format might have been smaller for easy transport in the field. Mr. Alston is to be congratulated and thanked for producing a work that will be most useful to field workers in the area, and it is to be hoped that the project of the remaining three Floras will not be allowed to lapse or be delayed for long.

Textbook of Organic Chemistry

By Prof. George Holmes Richter. Pp. viii+711. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 20s. net.

THIS book is designed for "ambitious students who wish to study beginning organic chemistry and gain more than a superficial knowledge of the subject". The author confesses that he has presented more material than can perhaps be covered in an average one-year course: some of it, indeed, would be deferred in Great Britain until the student had entered his honour year.

A short introductory chapter (8 pp.) is followed by a systematic description of aliphatic (451 pp.), aromatic (190 pp.), and heterocyclic (33 pp.) compounds. Alicyclic types are omitted. Although, on the whole, the treatment is sound, the ambitious

beginner will need to make great strides in order to keep pace with an exposition which introduces full structural formulae for vitamins A and D, cholesterol, and ergosterol, on pp. 78-79. Such statements as "van 't Hoff and Le Bel . . . were the first to suggest that the structure of the carbon atom was a tetrahedron" (p. 319) could be improved; and in the following instance (p. 324) the text is misleading: "The crystallization of a racemic mixture may lead to either one of two results: the crystals separating from the saturated solution may be a mixture of the crystals of the individual enantiomorphs; or the crystals may be the molecular complex . . . if the latter situation obtains, crystallization at a higher temperature will usually cause the molecular compound to break up into the two components which separate as individual crystals".

The book is well produced, with clearly printed formulae. J. R.

British Coracles and Irish Currachs: with a Note on the Quffah of Iraq

By James Hornell. (Published for the Society for Nautical Research.) Pp. xii+168+23 plates. (London: Bernard Quaritch, Ltd., 1938.) 7s. 6d. net.

IN this volume, Mr. Hornell reprints a series of articles which appeared originally in *The Mariner's Mirror*, the official publication of the Society for Nautical Research. It is, he points out, the first connected account of these interesting survivals of the primitive British boats, the coracle and the curragh, which are still to be seen on the rivers of Wales and the Welsh marches, and on the west coast of Ireland. In England and Scotland they are now extinct. The English coracle, the author holds, has a common ancestry with the quffah of Iraq, but is not related to the Irish curragh. This latter is of composite origin and a product of an indigenous Celtic development. Mr. Hornell discusses details of construction with the thoroughness he has taught us to expect from him in his studies of canoes and other craft.

The Universe of Science

By Prof. H. Levy. (The Thinker's Library, No. 67.) Revised and Expanded. Pp. xiii+242. (London: Watts and Co., 1938.) 1s. net.

THE publication of this inspiring essay in a popular series makes Prof. Levy's views accessible to a much wider public. This is in keeping with the author's main thesis that science is not something mysterious, but a weapon forged by man to extend control over Nature; and that as such it should be a mental and material possession of the common man. Even those who have read the first edition of this work will find it refreshing to ponder again over Prof. Levy's views on the processes of science, on the nature and role of mathematics and on determinism. At a time when the wealth of scientific discoveries is apt to confuse the mind of specialists and laymen as to the value of our knowledge, books such as the "Universe of Science" can perform a useful service in orientating and encouraging constructive thought. T. G.

Safety in Coal Mines

ON December 14, 1935, a Royal Commission under the chairmanship of Lord Rockley was appointed to inquire into what steps could be taken to improve the health and safety of workers in coal mines in Great Britain, having regard to the many changes that have taken place in organization, equipment and experience gained since the Coal Mines Regulation Act of 1911. The Commission held fifty-two public meetings, and after hearing evidence from the principal interests concerned, as well as visiting a number of mines, presented its report in December last*. The Government has announced that it has accepted the report as the basis for new legislation. The report itself extends to about 250,000 words and, in addition to a volume of appendixes, 1,500 pages of evidence involving nearly 37,000 questions and answers have been published.

Though lengthy and containing many details the report of the Commission is in general unanimous; the few reservations do not to any material extent affect its general tone. It is divided into twelve chapters each of which deals thoroughly with a phase of mining legislation or practice. The Commissioners have not examined exhaustively the details of the existing acts and regulations which form the present safety code, but instead have endeavoured to give the industry a new start by appealing to its sense of co-operation. They have attempted to frame a scheme for promoting a higher standard of safety which shall be positive or constructive rather than merely prohibitive or restrictive. The report is a considerate and reasonable document which in many respects differs fundamentally from the reports of the Royal Commissions on which the 1887 and 1911 Coal Mine Acts were based. These relied largely on compulsory compliance with rigid rules and regulations and tended to place the technical officers of the Department in the invidious position of being regarded by the industry as detectives instead of technical advisers.

If the suggestion of the Commission is to have any effect in reducing the accident rate in mines, a change of attitude to each other by all the partners in the industry, namely the administration, now the Mines Department of the Board of Trade, the coal owners, the colliery officials and the work people is essential. The point is emphasized that the problem of safety in mines, if substantial improvement is to be secured, must be attacked simultaneously from all sides by adequate

strengthening of the administration, the setting of a higher standard of enforcement or observance of regulations, an improvement in the material conditions under which work is carried out, and the co-operation of all parties. This will have the effect of imposing heavy duties on the shoulders of the administration and inspectorate, and heavy obligations on the owners and managing officials.

The majority of mine owners, engineers and workmen do everything that is humanly possible to encourage and maintain safe working conditions; but there remain some who, while paying lip service to the ideals, fall far short of them in practice. Until the standard of professional conduct of everybody working in coal mines rises to such a peak that deliberate evasion or lack of enthusiasm in enforcing safety principles is ostracized, no safety measures will be wholly effective. (By 'professional' is meant all classes, owners, managers, engineers, officials and workmen.) The only alternative to this voluntary change of attitude is a coercive policy as exemplified by 'thousands of regulations' or 'hordes of inspectors', a policy that the vast majority of mining men regard with despair.

The science and art of mining is in a state of constant change; quite literally, nothing is ever static in a mine, and it is to be hoped that the Mines Department, when framing the new Coal Mines Bill which will be drafted as the result of the Commission's deliberations, will pay due consideration to the recommendation that the Bill itself should be concerned with principles only, details being dealt with by orders and regulations which can be amended from time to time without having recourse to Parliament to meet the changing conditions in mines.

After a general introduction, the report gives a historical summary of the development of safety legislation in mines and traces briefly the origin and subsequent history of the mines inspectorate of Great Britain. It then goes on to discuss in detail various phases of mining organization, methods of working and ancillary operations as well as problems concerned with the preservation of health and the prevention of industrial diseases.

It is proposed that both the administrative staff at the Mines Department and the inspectorate should be strengthened and reorganized with a view of giving the Department and the inspectors a bigger sphere of activities, greater authority, wider powers and better opportunities of keeping in touch with the research stations. It is hoped

* Royal Commission on Safety in Coal Mines Report. (Omd. 5990.) Pp. xxxii + 520. (London: H.M. Stationery Office, 1938.) 7s. 6d. net.

that the senior inspectors will then be able to keep in closer personal touch with the mines in their districts and that, because of their opportunities of gaining wide experience of various mining problems, they may come to be regarded even more in an advisory capacity than has in fact been the custom heretofore. The chances of promotion and suggested general all-round increase in salary, combined with appointment by selection after interview instead of by written examination, ought to attract more experienced and better trained recruits into the ranks of the inspectorate. In the past, many men who wanted to become inspectors of mines, and if selected would have made good inspectors, have been afraid to enter into open competition against younger men owing to the time that has elapsed since they studied the fundamental sciences.

At the present time, the Mines Department, through the Board for Mining Examinations, controls the examinations for the certificates of competency that have to be held by colliery managers and under-managers in Great Britain. The Board was subjected to two kinds of criticism from witnesses, (a) against its present constitution, and (b) against the character of the examinations. It was pointed out that there is no system of rotational retirement and that no representative of any education authority or class of official other than the mine manager has a seat on the Board. The complaint about the character of the examinations was that they may allow candidates to pass without showing any real evidence of adequate scientific training. The Commissioners recommend the extension of statutory certificates to several other classes of officials besides managers, under-managers and surveyors and, as a consequence, propose that the present Board be reorganized into a central controlling board of seven members who shall retire in rotation. They further recommend that the Board might accept as fulfilling part of their requirements the examinations held by various technical societies or institutions. They also suggest that the new board should investigate the principle of compulsory attendance, by every candidate, at his local technical school or other institute. The Commission's second recommendation at present applies particularly to institutions which cater for officials junior to the colliery manager. The institutions concerned with other branches of engineering have their own professional examinations, but the Institution of Mining Engineers has so far held back.

The Commissioners have examined the whole question of mining research and suggest that a central research organization under the control of the Secretary for Mines ought to be an integral part of the Mines Department, with arrangements

for interchange and close co-operation between its staff, the staff of the Department's Testing Station and the inspectorate; at the present time, research in the mining industry is mainly financed by grants from the Safety in Mines Research Board, though a separate organization is maintained by the British Colliery Owners' Research Association, and numerous items of local interest are investigated by individual mining engineers and institutes.

The value of research is realized by the mining industry, but the results are not so well co-ordinated as they might be and take a long time to reach the individual colliery manager. Another point emphasized is that the majority of mining research work can be divided into two complementary sections, namely, that carried out in the laboratory and that in the mine respectively. The Commission is aware that a vast amount of possibly valuable information obtained in the laboratory at the research stations has not been translated into practice, and thinks that the Mines Department, through its research organizations, should be responsible for making arrangements for testing out in practice the results obtained in the laboratories. In this respect the close co-operation of the inspectorate would be invaluable.

Another matter of general interest in the report is health, and in particular silicosis, the incidence of which has greatly increased in recent years in portions of the South Wales coalfield. The Commissioners have recommended the use of definite and well-tried palliatives but, in view of the widespread, in fact international, interest that is being taken in the question, have not been too rigid in their conclusions. They are further agreed in recommending strongly that the Mines Department should employ a sufficient staff to ensure that the problem is pursued with the utmost vigour.

The Commissioners also recommend that a permanent 'General Staff' should be formed at the Mines Department with an advisory committee representative of all interests concerned to stimulate local safety propaganda, to collect, digest and circulate to similar voluntary organizations in each coalfield, material and ideas for a continuous safety campaign. They add that the principle of medical examination and certificates of fitness before employment should be applied to all young persons, and the minimum age of entry into a mine should be raised from fourteen to fifteen years. They also direct attention to the need of systematic training for all new entrants into the mining industry.

In the Commissioners' opinion, the amalgamation of mines into large and singly-owned groups renders necessary a redistribution of the statutory responsibilities of owners and managing officials,

so that the responsibility for safe working shall be fixed on those who have the effective powers of control and not solely, as at present, on the technical employees. Among the many technical recommendations relating to mining practice are important proposals for laying down and maintaining more definite standards of ventilation, for improving and intensifying the system of supporting the underground workings and securing the general application of the principles of roof control, which have been the subject of much recent research work, for improving the physical and material conditions under which haulage opera-

tions are conducted below ground, and for strengthening the precautions in connexion with explosives, electricity, shot-firing and coal dust.

In conclusion, while doubtless many of the recommendations of the Commissioners will be hotly debated when the new Bill is passing through the House of Commons, its most bitter opponent must acknowledge that the Commissioners have carried out their difficult task with moderation and vision. They have attempted to be helpful to everybody engaged in the production of coal, and appear to have held the scales of equity admirably.

J. A. S. RITSON.

Liquid Helium

By Dr. J. F. Allen, Royal Society Mond Laboratory, and
Dr. H. Jones, Imperial College, London

THE properties of liquid helium can best be considered under two headings: (a) properties in thermal equilibrium, (b) transport effects. The equilibrium properties, which have been the subject of many careful investigations in Leyden and elsewhere, may be regarded as fairly well established. These include the determination of the specific heat for different temperatures, the variation of density with temperature at different constant pressures, and the relation of the saturated vapour pressure to the absolute temperature scale. The investigations of transport effects such as the flow of the liquid through tubes, heat conductivity and associated effects are still in an early stage of development, and no clear understanding of these phenomena has yet been reached. The subject was discussed at a meeting following the International Refrigeration Congress in July, and also during the Cambridge meeting of the British Association. In this article we shall confine our attention largely to the interesting newly discovered transport effects, and give an account of recent experiments the results of which at present seem to find general acceptance.

EQUILIBRIUM PROPERTIES OF LIQUID HELIUM

Helium at atmospheric pressure liquefies at 4.22° K.; the critical temperature is 5.2° K. Generally speaking, the temperature range over which the properties of liquid helium have been measured extends only down to 1° K., since this is the lowest temperature conveniently reached by lowering the vapour pressure over the surface of the liquid. At 2.19° K. under its own vapour pressure,

liquid helium undergoes a remarkable transformation. As the liquid is cooled through 2.19° K., the specific heat jumps suddenly from a value of 0.4 cal. per gm. per degree to more than 5 cal. per gm. per degree, thereafter falling rapidly, approximately as T^2 . Simon has recently shown that at very low temperatures (0.02°–0.05° K.) produced by adiabatic demagnetization of iron ammonium alum, the specific heat of liquid helium varies as T^2 .

The transformation at 2.19° K. has also a remarkable effect on the expansion coefficient of liquid helium. Above that temperature it is positive, while below it is negative, although there is no discontinuity in the value of the density itself at 2.19° K.

Phase transformations of the type that liquid helium undergoes at 2.19° K. are known in other branches of physics; for example, the Curie-point transformation of a ferromagnetic, the order-disorder transformation of certain alloys, and the transition between the superconductive and the normal state of a metal. The temperature of the transformation in liquid helium is known as the λ -point, a name introduced by Ehrenfest. The modification of the liquid below the λ -point is generally referred to as helium II, that above the λ -point as helium I.

Liquid helium at 1° K. can be solidified under an external pressure of 25 atmospheres. At higher temperatures, greater pressures are required to produce the solid. The properties of liquid helium I are such as would be expected of an ordinary liquid of very low boiling point. It is far otherwise with liquid helium II. In the first place, it is an

immediate inference from the phase diagram that liquid helium II under its own vapour pressure remains liquid at absolute zero, for even in the neighbourhood of 1° K. the boundary line between the solid and liquid phases tends to become parallel with the temperature axis at a pressure of approximately 25 atmospheres. Since dp/dt (the slope of the boundary line) approaches zero as the temperature is lowered, and since the volume change, Δv , is not zero, it follows from Clapeyron's equation $dp/dt = \Delta s/\Delta v$, that Δs , the change in entropy on passing from liquid to solid, also approaches zero. There can thus exist the paradoxical situation of a liquid with zero entropy. On this account the possibility has been considered by several investigators that condensed helium at absolute zero has a space-ordered structure, and that the λ -point is of the nature of an order-disorder transformation.

An experimental investigation of this point has been carried out by Keesom and Taconis. They examined the reflection of X-rays in a column of liquid helium II at about 1.6° K., as well as in helium above the λ -point. No essential difference between the reflections in the two cases could be observed. Confirmation of the space-ordered theory, therefore, is still lacking, although it should be borne in mind that at 1.6° K. an appreciable degree of disorder would in any event be expected.

We may mention here that F. London, in a very interesting letter to NATURE, has recalled a prediction by Einstein that a perfect Bose gas at sufficiently low temperatures should show a discontinuity in the temperature derivative of the specific heat. Applying Einstein's formula to liquid helium, London shows that the discontinuity would occur at 3.09° K. Although Einstein's discontinuity is only in the temperature derivative of the specific heat, not in the specific heat itself, London suggests that there may be some connexion with the λ -point of liquid helium. The advantage of such a theory of the λ -point is that it appears not to necessitate a space-ordered structure for the liquid at low temperatures.

TRANSPORT EFFECTS

Flow Phenomena. Experiments designed to measure the viscosity of liquid helium II have led to the most surprising and apparently contradictory results. The first attempt in this direction was made at Toronto by Burton and Misener, who measured the damping of an oscillating cylinder immersed in the liquid. The value for the viscosity was found to drop suddenly at the λ -point from approximately 10^{-4} c.g.s. units for helium I to 10^{-6} c.g.s. units for helium II. Recent and more precise measurements by the similar method of an

oscillating disk, made by MacWood at Leyden, give values varying from 3×10^{-4} c.g.s. units for helium II just below the λ -point to 2×10^{-4} c.g.s. units at 1.1° K. Liquid helium II thus appears to be very much less effective in damping the motion of a body immersed in it than helium gas at room temperature.

Attempts to measure the viscosity of helium II by measuring the rate of flow through a tube were first made by Kapitza* and by Allen and Misener in the Royal Society Mond Laboratory at Cambridge. On account of the anticipated low viscosity, the latter used very narrow tubes to lessen the rate of flow, with the extraordinary result that the rate of flow was far in excess of what would occur in a liquid of viscosity 10^{-4} c.g.s. units. Moreover, the velocity of flow did not vary linearly with the pressure head. Kapitza found a velocity proportional to the square root of the pressure head, and interpreted this as evidence that the flow was turbulent. He gave a value of 10^{-4} c.g.s. units as an upper limit to the viscosity of helium II. Giaque in California has also observed the flow of helium II through an annular tube and has obtained a temperature variation of viscosity of from 10^{-4} to 10^{-6} c.g.s. units. Allen and Misener endeavoured to reduce the velocity of flow by using finer capillaries to obtain more nearly the condition for stream-line flow, and found that the rate of flow varied as a power of the pressure head of even less than one half. It was found that the dependence of velocity on the pressure head decreased with decreasing capillary size. For glass capillaries of 0.0015 cm. radius, it was found that the velocity varied as the $1/8$ power of the pressure, whilst for capillaries of 5×10^{-4} cm. in radius, obtained by packing a metal tube with parallel wires and then drawing the tube through dies, the velocity became absolutely independent of the driving pressure. In the latter case, the velocity increased very rapidly with decreasing temperature and reached a value of 20 cm. per second at 1.1° K. The flow also appears to be non-classical in the case of the variation of length of the capillary, since a variation of length by a factor of 70 produced only a fourfold change in the velocity.

On the other hand, experiments made by Burton in Toronto showed that with relatively wide and short tubes and rapid flow, the velocity is linearly proportional to the pressure head, and that the viscosity so determined agrees with the value obtained by the damping of oscillating disks. The anomalous features appear, therefore, when the flow takes place through very long and fine capillaries (radii less than 10^{-4} cm.).

*Actually Kapitza used the essentially similar method of radial flow between two parallel plates with small separation.

A little light is thrown on these curious results by the experiments of Mendelssohn and Daunt on the creep of liquid helium II in the form of mobile films over solid surfaces. If an open vessel be partially immersed in liquid helium II, it was observed that liquid gradually collected in the vessel until the liquid levels in vessel and bath were coincident. The rate of filling increased rapidly with lowering temperature. The mechanism was found to consist not in evaporation and recondensation, but in the transfer of liquid by means of surface films. At all temperatures in helium II the rate of transfer of liquid by means of the surface films was found to be independent of the difference in level. Both the thickness and the velocity of propagation of a film have been measured. The thickness is of order 5×10^{-6} cm. and the velocity increases from zero at the λ -point to 20 cm. per second at 1° K., which gives a rate of transfer of about 10^{-1} cubic centimetres per second per centimetre width of film. If films are formed above the λ -point, that is, by helium I, they are not more than 10^{-1} cm. thick.

A rough synthesis of the experimental results on flow of helium II can be attempted as follows. In flow through a tube, two distinct but by no means separate processes are taking place*: (a) the normal flow of a fluid with a viscosity (of order 10^{-4} c.g.s. units) which increases with decreasing temperature, and (b) creep along the inside walls of the tube by means of a surface film (of thickness of the order of 5×10^{-6} cm.), the velocity of which increases rapidly with decreasing temperature. For wide tubes, effect (a) predominates and the flow approximates to that of a normal viscous fluid. As the size of the capillary decreases, effect (b) becomes more pronounced, whilst for capillaries less than 10^{-4} cm. in radius, effect (a) becomes negligible and the quantity of liquid flowing per second is directly proportional to the circumference of the capillary.

Heat Conduction. The first experiments in the transport of heat through liquid helium II were made by Rollin and Keesom; their observations showed that helium II was a most efficient agent for the transport of heat, being far more effective than copper at the same temperature. It was observed later by Allen, Peierls and Uddin, and shown more convincingly by Keesom and Saris, that the rate of heat transport was not proportional to the temperature gradient. It is thus impossible to measure a true thermal conductivity for the liquid. The rate of heat transport is greater the smaller the gradient, and reaches a value corresponding to a conductivity several thousand times as great as that of copper at room temperature with gradients of the order of 10^{-3} of a degree per cm.

For a given gradient the 'conductivity' increases rapidly below the λ -point to a maximum at 2.0° K. and then falls again. Simon and Pickard of Oxford have found that the anomalously high conductivity disappears at the temperature at which the specific heat becomes normal.

Fountain Effect. The fountain effect, which was discovered in the Mond Laboratory, shows in the most striking manner the fundamental difference between helium II and any other known liquid. In its simplest form, the effect may be described as follows. A tube is partly immersed in helium II; the lower end of the tube is a capillary; both ends are open and an arrangement is made to heat the liquid in the upper part. A steady flow of heat is thereby maintained down the capillary. Under these conditions, it is observed that the liquid inside the tube rises above the level outside, showing the existence of a pressure in the reverse direction to the heat flow. A more spectacular demonstration can be given by placing powder in the lower half of the immersed tube through which the heat flows. To produce the heat current in this case, it is sufficient to shine light on the powder. With this arrangement the liquid may be made to rise right out of the tube, and in fact a steady 'fountain' several centimetres in height can easily be produced.

Quantitative measurements on the magnitude of the reaction pressure are very incomplete. Some data, however, are available from measurements* on the reaction to heat flowing in helium II through a tube filled with powder particles. The reaction pressure was found to attain a maximum value of approximately half an atmosphere for a gradient of 1° per cm. at 1.7° K. The value of the heat conductivity through the powder-filled tube was lower by a factor of a hundred than that through a smooth capillary of the same open cross-section. It seems, therefore, that the very large conductivity observed for helium II when the heat flows through smooth tubes is caused by violent convection currents which are set up by the reaction mechanism. This might be the reason for the apparent variation of conductivity with temperature gradient.

A complete understanding of the fountain effect must naturally await a satisfactory theory of the constitution of liquid helium II. However, a few interesting deductions can be made. In the first place, in the simple arrangement described above, the force holding the liquid above the bath level can only come from some form of interaction of the liquid with the walls of the tube or the attached heating wire. No other support is available, and the vapour pressure above the bath and inside the tube are sensibly the same. Secondly, this

*To be published shortly by J. F. Allen and A. D. Misener.

*Proc. Camb. Phil. Soc. (in the Press).

interaction must result in a downward thrust on the tube equal to the weight of liquid above the bath level. From the atomic point of view, this means that the interacting atoms are steadily transferring momentum in a downward direction to the tube, just as the thrust on the walls of a vessel containing gas implies that the atoms steadily lose momentum to the walls as they are reflected. This has the interesting consequence that the main heat transport in helium II at these temperatures (below 2.19° K.) cannot be due to the propagation of elastic waves as in ordinary liquids and solids, since elastic waves do not carry momentum.

Many and varied hypotheses have been made concerning the constitution of helium II. Michels, Bijl and de Boer and the present authors independently suggested that certain atoms which have more than the average energy in helium II

have, as well, a larger than average mean free path inside the liquid, and that heat flow represents a drift of these moving or 'excited' atoms. Later, this idea of energetic particles moving through the unexcited or 'condensed' atoms was developed by Tisza to include a theory of flow. This theory has not yet reached a quantitative stage, but has proved interesting and suggestive.

Note added in proof: Since this article was written, F. London has published (*Phys. Rev.*, 54, 947; 1938) an enlargement of the theory which he based on the consideration that helium at low temperatures exhibited Bose-Einstein condensation phenomena. His theoretical interpretation of the behaviour of liquid helium II appears to be quite in accordance with the experimental deductions given above, particularly with regard to the properties of flow of both heat and liquid.

The Earthquake in Chile

THE recent earthquake in Chile (*NATURE*, Feb. 4, p. 197) may justly be regarded as one of the greatest of such catastrophes in that country, and also in the world. According to local reports by survivors, the shock started about 11.35 p.m. local time on the night of January 24, and during the two or three minutes which it lasted ruined four towns and several villages, whilst doing severe damage to several others. The earthquake was felt from Valparaiso in the north to Puerto Montt in the south, the area affected now being estimated at 300,000 square miles. Large-scale damage was done from Talca in the north to Valdivia in the south, the area chiefly concerned being the province of Nuble, and the damage to property is estimated at £1,500,000. Altogether approximately 30,000 people were killed, 50,000 injured and there are about 100,000 homeless refugees.

At Chillan, a town of 45,000 inhabitants forty miles east of Concepcion, in the neighbourhood of the epicentre, two walls of the massive cathedral, the post office and telegraph building, the O'Higgins Infantry Barracks and most of the houses collapsed immediately. A theatre and a cinema collapsed, killing all the people inside. The hospital, although badly cracked, was one of the three or four buildings left standing after the initial shocks; but owing to the number of casualties the supply of anaesthetics ran out and the surgeons were obliged to operate without. Immediately after the shock the supply of electric power and

water ceased, so that the surviving firemen with the one remaining engine were powerless against the fires which followed. Moreover, transport was impossible on the railway and difficult on the roads around. After rescue operations, the Government ordered the evacuation of the town, it being estimated that here 10,000 lost their lives.

Parral, San Carlos and Egun, within the isoseismal 10, were also razed and evacuated. The villages of Retiro, Copihue, Zongavi, Bulnes and Quirihue were completely demolished. Andotro was very severely damaged, San Rosendo had 2,000 dead, and at Cauquennes, the town celebrated for its mineral springs, half the property including the hospital and prison was destroyed, killing 4,000 and injuring 800. At Concepcion, the fourth largest city in Chile, situated near the mouth of the Bio-Bio River and having a population of 89,000, three fifths of the city is in ruins and there are 2,000 dead. Many famous buildings, including the Teatro Campo Club and hospital, were destroyed. Here also a cinema collapsed killing 300 people inside it at the time, and fires added to the destruction in the city. It is expected that some of the fine modern buildings such as the Banco Central, the University and the Plaza Hotel which have been built to withstand earthquake shocks will have survived, unlike on the fifth occasion when Concepcion was completely destroyed on February 20, 1835. The damage was severe, but not so great at Los Angeles, Longavi and Linares. At Talcahuano, the port

and naval base, 19 are reported dead and 100 injured, fires adding to the destruction caused by the shock. At Talca many buildings were injured and the prison collapsed killing 10 convicts and injuring 20 others. Farther away, at Valparaíso, the church spire was damaged and at Santiago, 250 miles north of Concepción, the earthquake was strong enough to cause cracks in buildings.

Faulting has been on a considerable scale, and in the Province of Nuble the fissures caused by the earthquake are several kilometres long and often five metres deep.

So far as instrumental evidence is concerned, the shock was world shaking. At Santiago the shock was felt about 11.35 p.m. local time on January 24 (Jan. 25, 3h. 35m. G.C.T.). From Fordham, New York, the shock was reported double with an interval of 10 minutes between the shocks and the needle swung approximately eight inches for both shocks at maximum. It was recorded by instruments in Great Britain, and at Stuttgart in Germany the registration was complete, including *eP* at January 25, 3h. 46m. 51s., *ePP* 51m. 45s., *SKKS* 58m. 25s. and *LQ* at 4h. 25m. with $T = 50-55$ sec. all in G.C.T. At Hamburg one *eP'* was registered at 3h. 47m. 8s. and another at 50m. 49s., both on the vertical seismograph, *e₁PP* at 51m. 44s., *eL_{III}* at 4h. 20m. and *eL₂* at 4h. 24m. all in G.C.T. together with other pulses. Taking into consideration all the above evidence, it appears that the epicentre was near lat. $36^{\circ} 45' S.$ and long. $72^{\circ} 15' W.$, probably correct within 10 minutes of arc, that the depth of focus was normal and that for the first shock the origin time was January 25 at 3h. 32.0m. G.C.T.

Since the first shock, aftershocks have been frequent and often of considerable severity. The frequency and intensity has as usual in general

diminished, though there have been notable exceptions. There were severe disturbances on the night of January 27 and on January 28. On January 30, at 3h. 45m. G.C.T. a severe shock with the same epicentre occurred and completely demolished the three or four remaining buildings and walls at Chillan.

Sympathetic occurrences in the Andes probably due to the disturbance of the Chilean shock or resulting from the same deep initial cause are reported, including further earthquakes and tremors, and on January 29, the Mt. Lliama volcano was in eruption.

Further news of the catastrophe is expected in reports of the Chilean seismologists and geologists who left Santiago for the epicentral region immediately after the shock.

Obituary Notices

Prof. H. H. Woollard, F.R.S.

THE very sudden death of Prof. H. H. Woollard on June 18, at the age of forty-nine years, is a tragic loss for the science of anatomy in Great Britain.

Woollard was a product of the University of Melbourne, where he took his medical degree in 1910. During the Great War he saw active service with the Australian Army Medical Service and attained the rank of Lieut.-Colonel. After the War he intended to work for the fellowship of the Royal College of Surgeons, and to this end went to University College, London. Here he came under the inspiring influence of the late Sir Grafton Elliot Smith, an influence

which led him completely to change his original plans; for he now decided to take up the study of anatomy as a scientific career. He was appointed to the staff of the Department of Anatomy at University College, where he worked until 1928. He was afterwards appointed to the chair of anatomy and histology in the University of Adelaide, to the chair of anatomy at St. Bartholomew's Hospital Medical School, London, and finally as successor to his distinguished teacher Elliot Smith, in University College, London, in 1936.

Woollard's contributions to anatomy, direct and indirect, were outstanding. His early papers were mainly morphological in character, and of these may be mentioned an important and comprehensive

monograph on the anatomy of *Tarsius*, and comparative studies on the cerebral cortex of *Tarsius*, the brain of *Oryzomys*, and the retina of primates. He was, however, essentially an experimental anatomist, and he received a great stimulus from his contact with American anatomists during the year which he spent at Johns Hopkins University as a Rockefeller research fellow. As a consequence of the experience which he gained from this visit, Woollard published the results of several important experimental studies; for example, the development of the vascular patterns of the limbs as demonstrated by the micro-injection of living embryos, the phagocytic activity of haemal glands, and the vital staining of the leptomeninges. Probably some of his best work was that dealing with the innervation of the heart and blood vessels, which was completed in 1925 and 1926. In 1927 he published his "Recent Advances in Anatomy" which attracted vigorous attention to the development of experimental anatomy in other countries, and did much to stir his contemporary colleagues to work for the revivification and re-orientation of anatomical teaching and research in Great Britain.

During his brief tenure of office in the University of Adelaide, Woollard made full use of his opportunities by his detailed and original studies of the Australian brain and of the distribution of blood-groups among the native populations. On his return to England, he concentrated his research activities on the peripheral nervous system. He had acquired extraordinary skill with the difficult technique of vital staining with methylene blue, and he applied this technique to very good effect in his experimental studies of peripheral innervation. Mention has already been made of his work on the innervation of the heart and blood-vessels. This is work to which continual reference is made by those who are concerned with the neural control of the cardio-vascular system. He applied the same technical methods to problems of cutaneous innervation, and for this purpose he used himself as an experimental subject. He aimed at correlating the localization of different sensory spots in his own skin with different morphological types of nerve ending, a study which involved a considerable amount of discomfort in the small operations which he permitted to be carried out on himself in order to obtain material for histological examination. The results of some of these observations were published during 1936 and 1937, and in 1938 he was elected a fellow of the Royal Society.

Woollard died in the middle of a scientific career when he had already achieved much, but his research activities were so productive that his colleagues confidently looked forward to a great deal more from him and from those whose work he was directing in his department. More than this, he aspired to raise the science of anatomy to a level of achievement and activity which he regarded as its proper status. His energetic example had inspired many of his fellow anatomists to work with him to this end, and the first fruits of these efforts were already becoming evident. Hence, his death will be felt as an extremely serious loss for the subject which he represented.

His friends mourn a devoted worker who spared himself not at all in his scientific and departmental duties, a colleague who was always ready to give help and advice in all manner of difficulties, and a man who had a very lovable character.

W. E. LE GROE CLARK.

Mr. A. B. MacDowall

WE regret to record the death, which occurred on January 10, of Alexander Baird MacDowall, who was a frequent contributor to *NATURE* a generation ago.

Mr. MacDowall was born at Alloa on December 18, 1843. At fifteen years of age he was sent to the Old College in High Street, Glasgow, long since swept away, where he came into contact with Prof. W. Thomson, afterwards Lord Kelvin. Next he went to Berlin, returning after six months to take his degree at Glasgow. This was followed by a trip to Melbourne in a sailing vessel for reasons of health, the return journey being made via Cape Horn.

On his return to Great Britain, Mr. MacDowall settled in London and started upon a career of general journalism, working in the British Museum and at the Patent Office. There he met Sir William Harcourt, Thomas Carlyle and others, including D. E. Hughes, inventor of the microphone. He followed closely the development of the telephone, and long before it was in general use, he had an experimental installation set up in his house.

About this time, Mr. MacDowall was contributing to *NATURE*, and also to the Royal Meteorological Society, on the subject of terrestrial and solar meteorology and the relationship between them. In 1895 he brought out a small book "Weather and Disease: a Curve History of their Variations"; the mode of representation adopted was that commonly used at the time to illustrate the relation between two variables, namely, the production of smoothed curves recording the averages of five or ten consecutive values. A similar method was used in a paper on the relation of terrestrial weather statistics to the sunspot cycle presented to the Royal Meteorological Society in 1897.

In recent years, Mr. MacDowall travelled a good deal in the British Isles and on the Continent, settling down some twelve years ago at Rothesay in the Isle of Bute. He retained to the end his lively interest in scientific developments. His wife, Emily, a daughter of William Liddon and Emily Howard, died in 1935.

WE regret to announce the following deaths:

Paul Séjourné, free academician of the Paris Academy of Sciences, who was known for his work on the design and structure of bridges, aged eighty-seven years.

Prof. Josef Šimon, professor of roentgenology and radiology in the Masaryk University, Brno, aged forty-one years.

News and Views

A New Type of Nuclear Reaction

ON p. 251 of this issue of NATURE, an account is given of recent investigations by Prof. O. Hahn, Prof. L. Meitner and F. Strassmann on the bombardment of uranium by neutrons. Prof. Meitner and Dr. O. R. Frisch have discussed the development and implications of these results in a letter which also appears in this issue (p. 239). Experimental confirmation of these conclusions, it is claimed, is announced in the following cable, dated February 3, received from R. D. Fowler and R. W. Dodson, of the Chemical Laboratory, Johns Hopkins University. "We have bombarded uranium nitrate in a three millimetre ionization chamber with deuterium neutrons and found that particles causing a very intense ionization, at least five times that from natural uranium alpha particles, are produced. Fast neutrons from one milliamperere two hundred and fifty kilovolt deuterons produced thirty-five particles per minute. Placing paraffin around ionization chamber increases this to seventy counts per minute. We believe this to be confirmation of work of Hahn and Strassmann (*Naturwissenschaften*, Jan. 6; Frisch and Meitner NATURE [Feb. 11, p. 239—Editor]) in which activity ascribed to barium was found after neutron bombardment, and that these particles are barium ions of about one hundred million volts energy.

"We have also bombarded thorium oxide in similar ionization chamber, with deuterium neutrons. Fast neutrons in same intensity as above produce thirty intensely ionizing particles per minute. Paraffin does not increase the effect. We believe thorium is also disintegrated by fast neutrons into fragments of about one half thorium mass, having energies of about one hundred million volts."

Dr. W. D. Coolidge

THE Faraday Medal of the Institution of Electrical Engineers given annually "either for notable scientific or industrial achievement in Electrical Engineering or for conspicuous service rendered to the advancement of electrical science", has been awarded to Dr. W. D. Coolidge, director of the research laboratories of the General Electric Co., Schenectady. Dr. Coolidge was born in 1873, and educated at the Massachusetts Institute of Technology and at the University of Leipzig, studying especially physical chemistry. After holding certain academic posts, he joined the staff of the General Electric Co. in 1905, was promoted to be associate director in 1928 and in 1932 was appointed director of research. The name of Coolidge is associated with advances in many fields, but perhaps all his later work may be traced back to his important researches into the production of ductile tungsten, which revolutionized the design of electric lamps and had immediate applications in thermionic devices of several types. In the Coolidge X-ray tube, which was developed just before the Great War, the

tube was evacuated as thoroughly as possible and the electrons necessary to produce X-rays were emitted by tungsten filaments heated to a suitable temperature. In this tube, for the first time, the X-ray worker was able by simple means to control separately the voltage and current applied to his tube, while the steadiness of running and constancy of X-ray output were much greater than had been possible with the earlier ionic type of tube. Later, Coolidge developed tubes capable of operating at tensions up to a million volts in which the electrons were accelerated in stages. Somewhat similar tubes were made of such a design that the electron beam, instead of being intercepted by a target and producing X-rays, passed through a thin window and gave rise to remarkable fluorescent, chemical and biological effects, the possibilities of which have not yet been completely explored.

Josiah Willard Gibbs (1839-1903)

ON February 11 the centenary occurs of the birth of the distinguished American physicist, Josiah Willard Gibbs. Born at New Haven, he was the son of Josiah Gibbs (1790-1861), professor of sacred literature in Yale Divinity School. He entered Yale College in 1854 and graduated four years later; he continued his studies there until appointed a tutor in 1863. The years 1866-68 he spent in Paris, Berlin and Heidelberg. In 1871, he was appointed to the chair of mathematical physics in Yale College, and this appointment he held until his death, which occurred at New Haven on April 28, 1903. Gibbs' first contributions to mathematical physics were two papers on thermodynamical problems published in 1873. These papers were followed by his memoirs "On the Equilibrium of Heterogeneous Substances" published in two parts in 1876 and 1878. This was translated into German by Ostwald and into French by H. le Chatelier. He also investigated certain problems in connexion with the electromagnetic theory of light and other subjects. He was a foreign member of the Royal Society, and in 1901 received the Copley Medal. He was also a corresponding member of the Paris Academy of Sciences. At the anniversary meeting of the Royal Society when the award was announced, Sir William Huggins, the president, said that Gibbs "was the first to apply the sacred law of thermodynamics to the discussion of the relation between chemical, electrical and thermal energy and the capacity for external work. To chemistry his most important result is the so-called phase rule, the law which governs the general case of complete heterogeneous equilibrium and which is applicable to chemical change generally".

Refugee Settlement in British Guiana

THE United States has offered to send an expert Commission to investigate the possibilities of refugee settlement in British Guiana, and the offer has been

accepted by the British Government, who have appointed additional members to the Commission. The terms of reference of the Commission are: To study and report upon the suitability and practicability of large-scale colonization in British Guiana for involuntary emigrants of European origin, from the physical, climatic and economic points of view; to estimate the approximate numbers that might be settled there (a) immediately, (b) over a term of years; to calculate the probable cost of such settlement: if mass colonization appears feasible, to recommend a general plan of settlement. The names of the members are: Dr. Edward C. Ernst, assistant director, Pan-American Sanitary Bureau (chairman); Colonel Howard U. Nicholas, United States Army Engineering Corps, Panama Canal; Dr. Joseph A. Roese, Jewish colonization expert and agronomist; Mr. Emile C. Bataille, colonization expert with Canadian experience; Dr. Anthony Donovan, sanitary engineer; Mr. Desmond Holdridge, who has previous experience of the Colony (secretary). Sir Crawford Douglas-Jones, formerly Colonial Secretary of British Guiana; Sir Geoffrey Evans, formerly principal of the Imperial College of Tropical Agriculture, Trinidad, now economic botanist at the Royal Botanic Gardens, Kew. Dr. D. W. Duthie, agricultural chemist to the British Guiana Government, is being attached to the Commission for the purpose of advising and co-operating with the Commission.

Science and World Resources

THE December issue of *Fact* (No. 21. 6d.) contains a study "Science and World Resources" by Richard Palmer, which gives a comprehensive but readable survey of the way in which the world economy is changing under the impact of scientific advance. Mr. Palmer gives a dynamic picture of the way in which scientific discoveries and their technical development from synthetic dyes such as indigo and alizarin to synthetic rubber, the new textile fibres such as rayon and more recently 'Lanital' and 'Nylon' and the numerous synthetic resins or plastics, are influencing not merely the development of new industries or the displacement of old industries but also the distribution and availability of materials in the world, the location of industry, etc. Mr. Palmer's survey ranges over the whole field of materials, including beet sugar, alcohol, petroleum, coal, fertilizers, and light metals, and indicates admirably even to the non-technical reader the new freedom which the organic chemist is giving us and some of the possibilities if the new powers and opportunities are wisely used. Other chapters range over the possibilities in the way of power production which we owe to science and their significance in world economy, as well as the possibilities in agriculture and the way in which science has made it possible to improve working conditions and thus both industrial efficiency and the climatic or geographical zones within which effective production by human beings is possible. The essay provides an excellent background against which to discuss such current problems as those of raw materials and their bearing on the colonial question,

the limits of self-sufficiency policies, sanctions, economic nationalism and the like. The realistic picture he gives enforces the necessity for strengthening, while there is yet time, our efforts to create a social and international order in which knowledge will be used to the full in the service of all mankind.

The Empire Service Broadcasting Station

Mr. L. W. Hayes and Mr. R. N. MacLarty presented an interesting paper to the Institution of Electrical Engineers on February 2. They first gave an account of how broadcast transmissions with short waves initially started at the Chelmsford works of Marconi's Wireless Telegraphic Co. in 1927. This gave intelligible reception at practically every place on the earth's surface at almost every period of the day and year. A serious difficulty that had to be overcome was due to the wide difference in longitude of the different Dominions and Colonies of the British Empire. For this reason, a transmission sent out at a given time in England would arrive at very various local times of the night and day in the different Dominions. Broadly, the aim of the service is to give listeners anywhere in the Empire a daily programme of about two hours' duration; the installation of the new broadcasting service started in 1933 practically does this. Earlier than this, reports received in the West Indies also gave a service at the same time in Western Australia, and the announcement of "London calling the African and West African Zones" was being heard simultaneously at night in Africa, in the early evening in South America and the West Indies, and at breakfast time in New Zealand. This showed that dividing the earth into geographical zones could cause confusion. Accordingly, the daily transmission from the Empire Station at Daventry was divided into five sessions: Transmission No. 1, Transmission No. 2, etc., in accordance with a time schedule, the programme from the first zone being recorded and then transmitted at the most suitable times to the other zones. In 1935, a sixth transmission was added, primarily intended for evening listening in western Canada, but serving also North America generally and giving an early morning service to India.

Conditions of Engineering Contracts

THE subject-matter of an engineering contract necessitates that the documents of which the contract is composed must make provision for contingencies and events of a special nature. In this respect, it has peculiarities not to be found in other forms of contract, and is often inevitably of considerable length. The Council of the Institution of Civil Engineers asked Mr. E. J. Rimmer to write a paper on the subject which will be discussed by correspondence until May 15. The Council gave the author of this paper a very wide discretion in the choice of the title and in the scope of the paper. He has wisely chosen to give a comprehensive survey of the whole subject of engineering contracts. Many engineering contract works are to be constructed in, or erected and fixed on to, land. They cannot, therefore, be rejected and sent back to the contractor

if they prove to be unsatisfactory; the material and labour may have to be carried out in the open air with material and labour of varying quality; the conditions of excavation and foundation cannot be entirely foreseen until the ground is opened up; the execution of the works also may result in damage to property belonging to other persons. In addition, the completion of the work may extend over several years, and the employer may desire to use the completed parts of the work before the final completion of the whole.

It was formerly the custom to prohibit assignment and to allow subletting only when the previous permission of the engineer had been obtained. Recently it has become fairly common to provide a form to be attached to and filled up with the tender, upon which the contractor declares the names of the firms to which he desires to sub-let portions of the works, and if these firms are approved before the contract is sealed the contractor may straightway sublet work to these firms. The retention in the hands of the engineer of supreme power as sole arbitrator has, considering the terms and circumstances of present-day contracts, become rather an anachronism. Old forms change slowly and some of the reforms suggested are not quite satisfactory. In Mr. Rimmer's opinion, some phrases and clauses now accepted as standard practice are confusing and ambiguous. The basic conditions upon which standard conditions should be framed must first be decided by the parties concerned. If the persons have different views, they are sometimes determined on the basis of compromise. But if the conditions are to be clear and unambiguous, there is no room for compromise on the manner and phraseology on which these principles are to be stated.

Changing the Face of London

In his Friday evening discourse at the Royal Institution delivered on February 3, Sir Charles Bressy dealt with the question of "Bigger London or Better London?" He illustrated by lantern slides the growth of Greater London since the Great Fire and described the complex administration of the area, now that its population has reached $9\frac{1}{2}$ millions, equivalent to the entire population of Norway and Sweden. In twelve years time the population within a thirty-mile radius of Charing Cross may reach a 'peak' figure of $10\frac{1}{2}$ millions. Meanwhile growth continues with such alarming rapidity that the inadequacy of British road communications has necessitated the preparation of the Highway Development Survey published by the Minister of Transport last May. Its recommendations, looking thirty years ahead, include the construction of about 123 miles of new routes in the L.C.C. area, 368 miles outside the L.C.C. area (exclusive of motorways) and motorways to a total length of 307 miles. The total cost will lie between £180,000,000 and £230,000,000. Sir Charles stressed the urgent need for a new east-west route across London (the east-west connexion), for the completion of the South Circular Road, the formation of a loopway around the City, and the

extension of the Thames Embankment so as to form a continuous riverside promenade extending for eight miles from Putney Bridge to the Tower of London. The incessant congestion of London's main roads in time of peace was some inkling of what might happen if a hurried evacuation had to be undertaken. If the Government decides that the present time is not propitious for the undertaking of extensive works of road construction, nothing can justify the postponement of measures for safeguarding the course of new routes, which include tunnels adapted for use as part of London's air-raid defence schemes.

Sir Arthur Evans: Gifts to the Ashmolean Museum

SIR ARTHUR EVANS has presented to the Ashmolean Museum, Oxford, of which he was keeper for a period of twenty-five years ending in 1908, his unique collection of Minoan sealstones and gems, gold rings and jewels, as an accession to the recently rearranged 'Minoan Room'. The collection, as is recalled by the Oxford correspondent of *The Times* of February 2, is "far-famed and unrivalled", embracing every period and class of the Minoan gem-cutter's art—prisms, button-seals, cylinders and ring bezels in steatite, cornelian, ivory and other materials, engraved with pictographs, scenes of ritual, bull-fighting and other sports. Among the rings is the famous great gold ring of Nestor, the group of gold beads known as the Treasure of Thisbe, all engraved with scenes of ritual, combat and ancient legend. Since Sir Arthur began his archaeological explorations in Crete in the early nineties of the last century, both while he was keeper of the Museum and after, he has been liberal in contributing to its collections examples of the objects discovered by him in his excavations. With this latest gift, the Ashmolean collection of Minoan antiquities becomes the most important and the most complete outside Crete itself. Recent alterations of the Museum, in which the largest archaeological gallery has been divided into three sections, have made it possible for Sir Arthur, with the assistance of Miss Mercy Money-Coutts, to make a new installation of Cretan antiquities, in which the older collections have been supplemented by groups of casts, numerous photographs, diagrams and water-colour drawings, with figurines, smaller antiquities and pottery which he has transferred to the Museum from his private cabinets. His benefactions have not, however, been confined to the donation of antiquities from Crete. They include classical antiquities, large series of Greek, Roman and Anglo-Saxon coins, and other objects, as well as the great collections of stone and bronze implements, Anglo-Saxon jewellery and other material which belonged to his father, the late Sir John Evans.

Morbid Heredity in Isolated Communities

An interesting study of morbid heredity in man in an isolated community by Dr. J. W. McFeeters, for which the Sir Charles Hastings Clinical Prize for 1937 has been awarded (*Brit. Med. J.*, Feb. 4, p. 218), is made the basis of a suggestion that in view of the facilities for tracing family pedigrees in small isolated communities and the inbreeding imposed upon such

communities for generations, similar studies should be undertaken, distributed as widely as possible over the country; before improved communications break down this isolation. The present observations appear to bear out the author's contention that such a series of records is bound to throw light on the occurrence of rare recessive characters, which are much less likely to occur when random mating is the rule rather than the exception. The village here under study consisted of about fifteen hundred inhabitants. Observations of numerous morbid data extended over a period of years, and led to the conclusion that heredity plays an even more important part in many varied conditions than is generally recognized. Of the many conditions studied, eight were chosen for discussion—hereditary cerebellar ataxia, progressive muscular dystrophy, the lymphatic diathesis, otitis media, hernia, cancer of the bowel, rodent ulcer and hydranmios. Among the more significant points which emerge, it is noted that in progressive muscular dystrophy, the condition is definitely sex-linked. It is transmitted by apparently healthy females in three generations. In three cases it was associated with failure to bleed, a peculiarity not previously recorded in this connexion. The incidence of hernia is curiously restricted. Out of twenty cases, fifteen occurred in two families; and heredity evidently played a part even more important than strain. The possibility of the occurrence of a xgotic lethal factor in the male—a possibility suggested with some doubt by Ruggles Gates—receives support from the study of hydranmios, where there may be a relationship of the cases on the paternal, and not the maternal side.

Natural and Synthetic Fibres: Sisal and Flax

INTERESTING information on the development of natural and synthetic fibre industries is published in the *Journal of the Royal Society of Arts* (87, No. 4494). Discussing sisal and flax production in East Africa, Dr. W. H. Gibson maintains that the sisal industry is now well established in Kenya, binder twine and string being at present the chief uses for the fibre. Sisal is also finding a ready market for matting and upholstery filling, and tests regarding rope manufacture are giving satisfactory results. The flax industry in Kenya, on the other hand, has so far been less successful, due largely to the difficulties encountered in the process of retting, that is, the preliminary steeping process during which the fibres are loosened from the woody stem. Experiments recently carried out in the United Kingdom, however, have shown that it is possible to eliminate this process and extract the fibre from the natural flax, and with this discovery the way for the development of the industry in Kenya and other suitable parts of the Empire seems most promising.

THE modern counterpart of these vegetable fibres, namely, the synthetic textiles, are the subject of a paper by Dr. E. F. Armstrong. Artificial silk produced from wood pulp and its more recent development, staple fibre, are well-known supplements to, and competitors with, natural silk, wool and cotton. A new textile called 'Nylon' has, however, recently

been produced by the du Pont Laboratories in the United States. This thread is of an entirely different origin to rayon, as it is a plastic substance derived ultimately from coal tar, with dyeing properties akin to natural silk or wool, and it appears to have a most promising future. Two other types of fibre may be mentioned. The first is 'Lanital', an Italian product made from casein and used as a wool substitute, but as it lacks wet strength, attempts are being made to produce a better product from the protein of the soya bean. The second is spun glass which, though unsuitable for clothing, is used for electrical insulation, gas and liquid filtration and decorative purposes. In spite of the popularity of synthetic textiles, it is noteworthy that in 1937 the world production of these fibres was only in the ratio of 1.8 to 28 of natural spinning materials.

Forestry in Finland in 1937

THE annual report of forestry activities in Finland (XVII *Metsätilasto Forststatistik—Kartomus Metsähallinnon Toiminnasta* 5, 1937. *Berättelse över Forstförvaltningens Verksamhet*, Ar 1937), published in Helsinki last year, sums up the work of this progressive Forest Department. The great advance made by Finland since the Great War and the position she has taken in European forestry circles may to some extent be attributed to the fact that the Forest Department had a large forest capital at its back already under exploitation. Consequently a variety of problems were presented to the trained forester, from forestry education through sylvicultural management and protection down to the study of utilization, the improvements possible in extraction, statistics and prices, and so forth. The forestry reforms of 1921–23 prescribed the division of the country into four districts containing ten forest inspections and ninety cantonments (subdivisions of an inspection). Each district was administered by a local forestry bureau, under whom were the inspections, each in charge of an inspector. An important outcome of a decree of July 1934 is the gradual replacement of the untrained forest guards by *chefs de travail* or overseers, all of whom will have received training at one of the forestry schools, of which there are six. Considerable progress has been made with working plans and maps required in connexion with their preparation—revision of these plans is undertaken every ten years. The report deals in detail with the commercial activities, since the forests play so important a part in Finnish economy, and the British market is a very valuable one. An interesting point in the report is the policy undertaken by Government of settling a proportion of the population within the large forest areas owned by the State.

The Phenological Survey

THE new phenological forms distributed by the Royal Meteorological Society to its six-hundred-odd observers for 1939 have a further reconstruction of selected specimens of fauna and flora on a much more scientific basis. A noticeable feature is a considerable increase in the number of Lepidoptera selected for special observation, there being fifty selected

indigenous Lepidoptera the appearance of which is to be recorded, and three immigrants. This has been at the expense of a considerable reduction in the bird migration list, as many of those subjects had been reported on continuously for many years. There has been an extension in the selected observations on trees, chiefly in regard to leafing times. The modern system of Latin bird names is now used, although observers are warned that the old system is still used in some reference books. Particular stress is laid on the importance of recording the effects of abnormal weather upon the vegetation, etc. Spring and early summer appearance dates of the peacock and red admiral butterflies should help gather additional information regarding the question of their hibernation. A valuable addition to the recording of flowering of plants and leafing of trees is the recording, as well as the date, of the sheltered or open position of the plant. On the whole, the amount of observation called for has been considerably increased, but individual phenologists are encouraged to send in returns of any one group if they wish.

Norman Lockyer Observatory

Bulletin No. 2 of the Norman Lockyer Observatory, Sidmouth, recently issued, contains an appreciation of the late Sir Robert Mond, chairman of the Observatory Corporation for twenty-one years and a generous benefactor to the Observatory. A further note of a personal nature gives an account of the unveiling of the memorial to the late director, Dr. W. J. S. Lockyer, at which Sir Robert Mond presided just three months before his death. Part of the memorial alluded to is the Oxford microphotometer, a description of which is given in the present *Bulletin* by the director, Mr. D. L. Edwards, together with illustrations of representative tracings of stellar spectra and of several line-contours, obtained with the instrument. Mr. D. R. Barber contributes two papers. The first is a detailed account of the magnificent auroral display of January 25, 1938, which appears to have been visible over practically the whole of Europe and the North American continent. The second paper deals with the objective prism-spectra of Finsler's Comet obtained at its apparition of 1937. In a preliminary investigation (N.L.O. *Bull.*, No. 1), Barber had found that a visual comparison of the intensities of the cometary bands at 4700 and 3880 Å. due to O(IV) and CN(IV) radiation respectively indicated that the former was about $2\frac{1}{2}$ times stronger than the latter, a result in the opposite direction from that deduced from slit spectrograms secured at the Mt. Wilson and the Lick Observatories. The Sidmouth spectrograms have now been analysed by means of the new microphotometer, and Barker confirms his first result with, however, a reduction of the ratio of relative intensities from $2\frac{1}{2} : 1$ to $1\frac{1}{2} : 1$.

Literature for Adult Education

AN important factor in the success of discussion groups or public lectures as a means of education for citizenship is the provision of books and other

suitable material for reading. A pamphlet, "Printed Page and the Public Platform", which has recently been issued by the Office of Education, United States Department of the Interior (Washington, D.C.: Gov. Printing Office, 20 cents), analyses the different factors involved and gives an account of experiments and experience in the United States which should be highly useful to those interested in adult education in Great Britain. The necessity for close co-operation between libraries and such discussion groups is emphasized, and a number of practical suggestions are detailed to facilitate co-operation. The scope and functions of reading lists are critically discussed and the importance of having the reading material as accessible as possible to those taking part in the discussions or attending lectures is recognized. Equally important is the suitability of the material, and while the criticism is not specifically directed at scientific literature, it applies equally to that intended for the general public. Able exposition is a first condition of success, involving an understanding not only of the subject handled but also of the readers to whom the book or article is addressed, and if pamphlet literature admittedly presents special difficulties, the problem is one which deserves greater attention because of its greater appeal to many readers in spite of the distribution difficulty.

The International Seismological Summary

THE I.S.S., compiled at Oxford, is a work which increases in volume and range as it progresses. The volume for January, February and March 1933, which commences the sixteenth volume, has just appeared, and deals with 165 epicentres, 67 being new and 98 repetitions from old epicentres. Nine of the earthquakes mentioned have foci which are below normal. The epicentres have, in general, been determined from observations of *P* alone, instead of by the old method of using *S*—*P* differences. This is said to make very little difference in the case of well-observed earthquakes, but is greatly to be preferred on theoretical grounds. During the last five years, the range of numbers of earthquakes with determinable epicentres recorded in the I.S.S. has been from 569 in 1932 to 653 in 1930. It appears, therefore, that notwithstanding the greater number of stations sending readings, and the greatly improved registration, the numbers of such earthquakes have reached a probable limit. In this volume, stations which send additional readings to the usual *P*, *S*, *L* and *M* are thanked especially, and for the future all are requested to classify wherever possible their *L* readings into *LQ* and *LB*, and to state whether the initial *P* reading is compressional or dilatational.

The Medical Press and Circular

THE issue of January 25 of the *Medical Press and Circular* is a centenary double number. This journal is, as the name suggests, the combination of two, namely, the *Dublin Medical Press*, founded in Dublin in 1839, and the *Medical Circular*, founded in London in 1852, the union taking place in 1866. Prof. Rowlette of Dublin contributes a short history of the journal during the hundred years, with biographical

notes on the various editors. Dr. Cecil Wall and Mr. Walter Spencer discuss the progress of medicine and of surgery, respectively, during the period; an illustrated article on "Some Medical Celebrities of the Victorian Age", as depicted in cartoons of *Vanity Fair*, is contributed by Sir St. Clair Thomson, the cartoons being reproduced together with actual portraits; and a chronological list of medical societies and journals in Great Britain and Ireland is furnished by Mr. Reginald West. Other articles and reviews complete a very interesting number.

Art and Psychiatry

UNDER the auspices of the Government Federal Art Project and of the Bellevue Hospital psychiatric department, the Harlem Art Centre in New York City has organized the first exhibition of its kind in the United States, consisting of pictures showing the work of disordered minds. The artists include moronic children; chronic alcoholics, advanced epileptics, manic-depressives and general paralytics. Most of the exhibits indicate mental conflict, being shapeless, lurid and grotesque. The idea underlying the art classes at Bellevue Hospital is to attempt a cure of the mentally sick by encouraging them to express their conflicts and at the same time to give psychiatrists a clearer picture of their patients' emotional life.

Earthquake in Ecuador

SEVERAL earthquakes of sufficient intensity to crack buildings shook a considerable area in Ecuador on the night of February 1, 1939. Altogether nine tremors were felt at Valledumbos and four other towns, and five tremors at Quito. Quito was ruined with the loss of 40,000 lives on February 7, 1797, and simultaneously there was volcanic eruption in Guadeloupe. In the present instance, Cotopaxi, the highest volcano in the world, is in eruption. It was in 1768 and 1877 that previous disastrous eruptions of Cotopaxi took place.

Announcements

THE council of the Institution of Electrical Engineers has elected Sir Archibald Page, chairman of the Central Electricity Board, and a former president of the Institution, to be an honorary member.

M. EMMANUEL DE MARGHERIE has been elected a member of the Section of Mineralogy of the Paris Academy of Sciences in succession to the late L. de Launay.

THE Goethe Medal for Art and Science has been awarded by the German Chancellor to Dr. Theodor Kitt, professor of veterinary pathology in the University of Munich.

RESEARCH CORPORATION, of 405 Lexington Avenue, New York, from time to time makes awards to universities for the work of men of science. The Corporation has now made grants to Columbia University, New York, of 2,500 dollars each and Research Corporation plaques, to be made the basis

of awards to (1) Dr. H. S. Taylor, of Princeton University, "for his work in the field of catalysis, wherein he has advanced the theory of catalytic action and the art of using catalysts in industrial operations in this field"; (2) Dr. V. Bush, of Massachusetts Institute of Technology, for his work "in the development of powerful and rapid methods of computation and the solution of equations through the invention of automatic apparatus".

ON December 22, the French Minister of Public Health inaugurated the new laboratories of the Pasteur Institute at Garches near Paris where Pasteur made his studies on rabies in 1884.

THE King has commanded that the recently founded British College of Obstetricians and Gynaecologists shall be known as the Royal College of Obstetricians and Gynaecologists.

THE Royal Sanitary Institute will hold its Annual Congress at Scarborough on July 3-8 under the presidency of the Earl of Harewood. Further information can be obtained from the Secretary of the Institute, 90 Buckingham Palace Road, S.W.1.

THE sixth Biennial Congress of the International Hospitals Association will be held at Toronto next September. Further information can be obtained from the Secretaries of the Association, 17 Bloomsbury Square, W.C.1.

THE Mary Putnam Jacobi fellowship of 1000 dollars is offered to a woman graduate of an approved medical school for post-graduate work in the medical sciences. If the appointed fellow is not resident in the United States, she should preferably undertake work there. Applications should be sent to the Secretary of the Fellowship Committee, Dr. Phebe L. DuBois, 150 East 73rd Street, New York City, before April 1.

THE German Society for Balneology and Climatology will hold its annual meeting at Vienna on March 23-26, when the following subjects, among others, will be discussed: meteorological and physical report; medical report, importance of high mountain climate in treatment of tuberculosis and asthma; physiology of sport in high mountains; drinking wells and artificial salts; natural and artificial mud baths; and artificial climate. Further information can be obtained from Die Reichsanstalt für das deutsche Bäderwesen, Fürstenstrasse 124, Breslau 16.

THE annual mortality from malaria in India averages 2,000,000, an exceedingly high figure even in a population of more than 300,000,000, 30 per cent of whom suffer from the disease. Two thirds of the malaria-stricken in India have no quinine.

ERRATUM.—In NATURE of January 7, p. 23, "A Rapid Visual Test for Vitamin A Deficiency", para. 4, last sentence, for "hemeralopia" read "hemeralopia".

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 247.

Disintegration of Uranium by Neutrons: a New Type of Nuclear Reaction

On bombarding uranium with neutrons, Fermi and collaborators¹ found that at least four radioactive substances were produced, to two of which atomic numbers larger than 92 were ascribed. Further investigations² demonstrated the existence of at least nine radioactive periods, six of which were assigned to elements beyond uranium, and nuclear isomerism had to be assumed in order to account for their chemical behaviour together with their genetic relations.

In making chemical assignments, it was always assumed that these radioactive bodies had atomic numbers near that of the element bombarded, since only particles with one or two charges were known to be emitted from nuclei. A body, for example, with similar properties to those of osmium was assumed to be eka-osmium ($Z = 94$) rather than osmium ($Z = 76$) or ruthenium ($Z = 44$).

Following up an observation of Curie and Savitch³, Hahn and Strassmann⁴ found that a group of at least three radioactive bodies, formed from uranium under neutron bombardment, were chemically similar to barium and, therefore, presumably isotopic with radium. Further investigation⁵, however, showed that it was impossible to separate these bodies from barium (although mesothorium, an isotope of radium, was readily separated in the same experiment), so that Hahn and Strassmann were forced to conclude that isotopes of barium ($Z = 56$) are formed as a consequence of the bombardment of uranium ($Z = 92$) with neutrons.

At first sight, this result seems very hard to understand. The formation of elements much below uranium has been considered before, but was always rejected for physical reasons, so long as the chemical evidence was not entirely clear cut. The emission, within a short time, of a large number of charged particles may be regarded as excluded by the small penetrability of the 'Coulomb barrier', indicated by Gamov's theory of alpha decay.

On the basis, however, of present ideas about the behaviour of heavy nuclei⁶, an entirely different and essentially classical picture of these new disintegration processes suggests itself. On account of their close packing and strong energy exchange, the particles in a heavy nucleus would be expected to move in a collective way which has some resemblance to the movement of a liquid drop. If the movement is made sufficiently violent by adding energy, such a drop may divide itself into two smaller drops.

In the discussion of the energies involved in the deformation of nuclei, the concept of surface tension of nuclear matter has been used⁷ and its value has been estimated from simple considerations regarding nuclear forces. It must be remembered, however,

that the surface tension of a charged droplet is diminished by its charge, and a rough estimate shows that the surface tension of nuclei, decreasing with increasing nuclear charge, may become zero for atomic numbers of the order of 100.

It seems therefore possible that the uranium nucleus has only small stability of form, and may, after neutron capture, divide itself into two nuclei of roughly equal size (the precise ratio of sizes depending on finer structural features and perhaps partly on chance). These two nuclei will repel each other and should gain a total kinetic energy of c. 200 Mev., as calculated from nuclear radius and charge. This amount of energy may actually be expected to be available from the difference in packing fraction between uranium and the elements in the middle of the periodic system. The whole 'fission' process can thus be described in an essentially classical way, without having to consider quantum-mechanical 'tunnel effects', which would actually be extremely small, on account of the large masses involved.

After division, the high neutron/proton ratio of uranium will tend to readjust itself by beta decay to the lower value suitable for lighter elements. Probably each part will thus give rise to a chain of disintegrations. If one of the parts is an isotope of barium⁸, the other will be krypton ($Z = 92 - 56$), which might decay through rubidium, strontium and yttrium to zirconium. Perhaps one or two of the supposed barium-lanthanum-cerium chains are then actually strontium-yttrium-zirconium chains.

It is possible⁹, and seems to us rather probable, that the periods which have been ascribed to elements beyond uranium are also due to light elements. From the chemical evidence, the two short periods (10 sec. and 40 sec.) so far ascribed to ²³³U might be masureum isotopes ($Z = 48$) decaying through ruthenium, rhodium, palladium and silver into cadmium.

In all these cases it might not be necessary to assume nuclear isomerism; but the different radioactive periods belonging to the same chemical element may then be attributed to different isotopes of this element, since varying proportions of neutrons may be given to the two parts of the uranium nucleus.

By bombarding thorium with neutrons, activities are obtained which have been ascribed to radium and actinium isotopes¹⁰. Some of these periods are approximately equal to periods of barium and lanthanum isotopes¹¹ resulting from the bombardment of uranium. We should therefore like to suggest that these periods are due to a 'fission' of thorium which is like that of uranium and results partly in the same products. Of course, it would be especially interesting if one could obtain one of these products from a light element, for example, by means of neutron capture.

It might be mentioned that the body with half-life 24 min.¹ which was chemically identified with uranium is probably really ²³⁸U, and goes over into an eka-rhenium which appears inactive but may decay slowly, probably with emission of alpha particles. (From inspection of the natural radioactive elements, ²³⁸U cannot be expected to give more than one or two beta decays; the long chain of observed decays has always puzzled us.) The formation of this body is a typical resonance process²; the compound state must have a life-time a million times longer than the time it would take the nucleus to divide itself. Perhaps this state corresponds to some highly symmetrical type of motion of nuclear matter which does not favour 'fission' of the nucleus.

A Novel Thermostat

It is often necessary to maintain an apparatus at a constant temperature. This may be done by immersing it in a circulating liquid maintained at a constant temperature by a thermostat, or by jacketing

TEMPERATURE-CONTROLLED APPARATUS.

it with alternate shells of thermally conducting and insulating materials heated to the selected temperature by means of an internal electric heater. These methods have the disadvantages that the thermostat system makes the apparatus less accessible, the

control of the temperature to within a narrow range requires some complication in the whole system, and it is difficult to prevent 'hunting'.

In a measurement which we are making of the electronic charge, it is necessary to maintain the temperature of the air, in which an oil drop moves, uniform and constant so that it has no motion due to convection. As a convenient solution of this problem has been found which seems capable of many applications, it is described here.

A resistance thermometer is formed by winding a single layer coil of copper wire around and in good thermal contact with the microscope condenser which forms part of the apparatus the temperature of which is under control. (In the accompanying illustration the condenser tube is on the right.) This coil forms one arm of a Wheatstone bridge, the other arms being of manganin resistances. Any change in temperature of the apparatus deflects the light spot of the galvanometer connected to this bridge, and for one direction of deflection the spot falls on a photo-electric cell, which operates a polarized relay, which in turn puts off two 30-watt lamps placed on opposite sides of the apparatus. The amplification of the galvanometer current by the photo-electric cell is 10⁶, and including the relay about 10⁷.

The bridge is adjusted to be balanced at a temperature a few degrees above the maximum temperature to which the room rises during a day. The lamps flash on and off every few seconds and maintain the temperature of the external surface of the apparatus constant to about 0.002° C. After the thermostat has been in operation for an hour, we have not been able to detect, by means of a thermocouple, any change of temperature inside the apparatus.

Limitations on the Modern Tensor Scheme of Relativity

It does not appear to have been noticed by anybody that the tensor scheme of relativity is incompetent by itself to include relations of chirality, to use Lord Kelvin's term. For it is developed from a pure Riemannian geometry, as based solely on the use of an ideal mobile a-chiral linear measuring rule. The meaning of relativity has, of course, always been that knowledge consists of the relations of one system to another, especially when one type of system of high simplicity, such as the linear measuring rule, is taken as the standard of comparison for all others. This significance of the chiral property, which is the difference between a chiral system and its mirror-image, for example, between a right-hand glove and a left-hand, goes back to Kant's early writings, and remained fundamental in his trains of thought in relation to space and time; later, in the more amateur hands of Pasteur, it created a fundamental science. Chiral systems can be compared completely only with chiral systems. The frame of reference for a chiral system must itself have chiral property; for example, to be effective, the mobile measuring rod of Einstein would require to possess a screw structure essential to it. When Newton explained how he could tell by experiment

whether his space was rotating, he was perhaps not so far out after all.

It may appear that this argument presents a demurrer to the theory which derives the space-time scheme from the single mental foundation of linear succession in a time which is absolute for all observers everywhere: but it is to be remembered that the assertion of a scalar constant velocity of radiation is there the fundamental postulate. Chiral properties, of the two conjugate types, would thus have to be restricted to imbedded atomic structures. Likewise to our universe based mainly on negative electrons there ought in theory to be a conjugate universe, its mirror-image, based on positive: and to our organic nature based on leval chiral structures there ought in theory to be a conjugate one, its mirror-image, based on dextral.

On the other hand, it is perhaps not easy to see how the tensors can escape the fate that is reserved for all 'unobservable', unless a set of observing apparatus can be devised which is itself beyond the bounds of space and time.

Or may we find refuge in the doctrine that physical science, being concerned largely with statistical aggregates, is unable to construct laws or relations without allowing substantial margins for inherent 'uncertainties' (cf. Laplace on "Probabilities").

Also, co-ordinates must surely be defined or restricted by laws of continuity. All significant tensors would have to be invariant for every linear vector change in the frame of reference; but their components would by no means be separately invariant, thus the energy in a generalized sense which is the final component of the energy-tensor would have no reality. Yet notwithstanding this want of detailed invariance, the vanishing of the complete tensor involves (after Einstein) the separate vanishing of all its components, so would express one law of Nature built on this type, by a representative group of as many simultaneous differential equations as the vanishings provide.

Theory of Mesons and Nuclear Forces

As was first pointed out by Yukawa, it is in principle possible to account for the short-range forces between nuclear particles by the assumption of virtual emission and absorption processes involving intermediary particles of integral spin, the so-called *mesons*¹, the mass of which is determined by the range of the forces. As has been shown by Kemmer², the simplest wave-equations for the mesons which satisfy, besides the claim of relativistic invariance, the condition of giving a positive definite expression for the energy, reduce to four types, characterized by different co-variance properties of the wave-functions, and each allowing the existence of neutral as well as positively and negatively charged mesons. Starting from such wave-equations, including the interaction of the meson field with the heavy nuclear constituents, the estimation of the resulting expressions for the nuclear forces has hitherto been carried out by using the ordinary perturbation method of quantum theory, and taking into consideration only the first non-vanishing approximation, in spite of the well-known lack of convergence of the method.

It would thus seem desirable to discuss more closely the reliability of such results, and for this purpose a possible method of attack is suggested by an analogous situation in quantum electrodynamics, where a suitable canonical transformation allows us to separate, from the expression of the total energy of a system consisting of electrons and an electromagnetic field, a term depending only on the co-ordinates of the electrons and representing the Coulomb potential energy.

A similar method³ is, actually, applicable to a system consisting of nuclear particles and a meson field. For such a system it is, in fact, possible to find canonical transformations effecting the separation of a 'static' interaction between the nuclear particles, defined as the part of the interaction which is obtained when one neglects the time-variations of the variables characterizing the positions, spins and proton or neutron states of the heavy particles. This static interaction is in all cases exactly the same as that obtained as a first approximation in the perturbation method, and there exists a lower limit, smaller but unfortunately not much smaller, than the range of the nuclear forces, to the mutual distances between two heavy particles for which the static interaction is more important than the additional non-static contributions arising from the terms, in the transformed Hamiltonian, which describe the remaining interactions between the heavy particles and the meson field.

Although no improvement can, of course, be obtained in this way as regards the self-energy difficulties, it would seem that consistent results can be derived from the transformed Hamiltonian by considering only the last-mentioned interactions as a perturbation and applying a method of treatment analogous to the correspondence methods used in electrodynamics. It is especially to be noted that if, following Yukawa, we also introduce an interaction between the meson field and electrons and neutrinos, the transformed Hamiltonian contains a term which represents a direct interaction between the heavy particles and the electrons and neutrinos, and which, when treated as a small perturbation, immediately gives the probabilities of β -disintegration processes. It is perhaps to be regarded as a satisfactory feature of the point of view just outlined that, contrary to previous treatments, where the nuclear forces came out in the same stage of the perturbation method as the probabilities of β -decay, account is here taken at the outset of at least the static part of the nuclear forces.

As regards the form of these static interactions, it is well known that the type of potential resulting from the four-vector meson field generally considered hitherto has the defect of including a term of dipole interaction energy which is so strongly singular for infinitely small mutual distances of the nuclear particles that it would not in general allow the existence of stationary states for a system of such particles. In order to remedy this defect, it seems necessary⁴ to introduce besides the four-vector wave-function a further pseudoscalar wave-function for the meson field which has the property of giving rise to a static interaction of a form just capable of cancelling the dipole interaction term without affecting the others. The consideration of such a pseudoscalar meson field would also seem to be useful from the point of view of the theory of β -decay. While, for example, the four-vector theory yields⁴ exactly the same form of the β -spectrum as Fermi's original

theory, the introduction of a pseudoscalar wave-function in addition to the four-vector one gives rise to a modification of the energy distribution of the β -rays which seems to open a new possibility of a better adaptation to the experimental results.

A detailed account of our work will appear shortly in the *Proceedings of the Copenhagen Academy*.

Frequency Interpretations in Probability

THE letter of mine quoted by Dr. W. E. Deming¹ was mostly in the nature of a personal explanation. I have never denied that frequencies may be *relevant* to a prior probability; what I deny is that a frequency is ever the *whole content* of a probability, whether prior, direct or posterior. I have, in fact, pointed out that prior probabilities should be reassessed from time to time to allow for accumulation of information from analogous problems, and the case considered by Deming is an extreme one of this type, since the balls in his box are derived from a large population the composition of which is definitely known. The kind of distinction involved seems to have been noticed by Laplace, if one compares his opening remarks with those of De Moivre. De Moivre begins by defining a probability as simply the ratio of the number of favourable cases to the whole number of possible cases. Laplace puts in the proviso "provided that all the cases are equally possible"; otherwise his statement is practically a translation of De Moivre's.

Consider the following problem. A box contains one white and two black balls; another contains one white and one black. A box is to be chosen at random and then a ball at random from that box. What is the probability that the ball will be white? According to De Moivre's definition, it is the number of white balls divided by the whole number of balls, and therefore is $2/5$. All balls are possible and there is no alternative. But I think that any modern writer would say that the probability is $\frac{1}{2} \cdot \frac{1}{2} + \frac{1}{2} \cdot \frac{1}{2} = 5/12$, and indeed that De Moivre would have said so if the point was put to him. The correct result can be got only by recognizing that the five balls are not "equally possible". Though Laplace is liable to be too brief in places and by modern standards too prolix in others, I think it must be inferred from the comparison of the statements that he had seen that the earlier definition did not cover actual needs, and could be made to cover them only by means of the idea of "equally possible", which is not defined as such. It cannot be defined in terms of frequency and must be taken as a primitive notion.

Now Dr. Deming's presentation involves the same idea, through the notion of randomness, which is not defined. A mere statement of the numbers in the parent population is not enough to ensure randomness. For example, some adhesive might be present that sticks to the white balls and not to the black

ones. Then the extraction of a white ball would tend to pull others to the top, and we should expect a disproportionate number of white balls in a large sample, even although we might be unable to rule out any particular selection as impossible. In fact, the force of the treatment is not in the ratio of the numbers, but in the undefined notion of randomness, which is equivalent to "equally possible"—that is, that all selections from the parent population are equally likely. Without this idea, which may be part of a frequency treatment, but is not part of a frequency definition, we cannot say anything about what the result of a trial is likely to be. If anybody says that we will go on picking out white balls until there is none left, a frequency interpretation by itself provides no answer. It is possible in logic and there the matter ends. Similarly, no meaning could be attached to differences of possible biases in a coin; so long as it is in the least possible for either a head or a tail to occur, the probability, on the frequency definition, is $\frac{1}{2}$.

Of course I agree that there are cases where it is reasonable to expect that the ratio in a large sample will approximate to that in the population; but my point is that if we do that, we are taking "reasonable to expect" as a primitive idea, and it should be stated as such. No practical recommendation can ever be used unless this idea is brought in, though it is liable not to be mentioned by the statistician. That makes no difference in practice because, even if the statistician does not mention it, the person advised uses it. Without it, the latter would be entitled to say: "That is all very well as a piece of pure mathematics, but what has it to do with me?"

I should say myself that the hypothesis of randomness is always what logicians call a *considered* proposition, not an *asserted* one. The point of any type of significance test is to examine cases where the hypothesis may be untrue. It may in fact always be false—if a coin is thrown enough times it will wear and become biased; if a pack of cards is dealt often enough it will become marked and too many aces will go to the dealer, and so on. But it has the advantage that it involves the minimum number of parameters, since it does not need the introduction of one or more parameters to express possible bias or dependence of one trial on the results of previous trials. Consequently it is easy to state, and in actual cases easily discarded if it is found to be unsatisfactory; even if it is untrue it points the easiest way of progress. But it should not be stated as a fact, and if anybody proposes, in order that a frequency definition may give acceptable answers, to restrict himself to cases where randomness holds, he is both using the notion of reasonable degree of belief and artificially restricting its application.

Antarctica and Glacial Ages

PROF. A. P. COLEMAN¹ contends that the late Palaeozoic glacials of the southern hemisphere could never have been formed upon a large, single continent—Gondwana—as visualized by supporters of the hypothesis of continental drift. He has protested that, for such an ice-cap to have developed, there must have been sources of evaporation at hand in

the shape of warm seas, and has accordingly denied the existence of any such continent and along with it the hypothesis of drift. It is difficult to follow his argument in the face of recent work on this problem.

The mere presence of sea—whether warm or cold—would be no measure of the rainfall upon the adjacent lands, as witness the large desert regions along the coasts of South America, Africa and Arabia. A more important part must be played by the atmospheric circulation.

The coldest place in the world, stated by Prof. Coleman to have escaped glaciation during the Pleistocene, is situated right between the Arctic Ocean and the Sea of Okhotsk, only a short distance from either. The centre of the mighty Antarctic ice-cap is fully 1,500 miles from the encircling chilly ocean, where evaporation cannot surely be large.

According to Antevs the Pleistocene ice-cap was several times larger, but, even assuming with Prof. Coleman that the North American portion was unconnected with those of Europe or the Arctic, that body was still more than two thousand miles across, wholly eccentric to the pole and bounded on the south by a wide strip of continent.

It would seem not unreasonable to argue that during a major glacial period ice could have accumulated in a co-polar position up to at least two thousand miles back from the ocean margin, provided that the atmospheric and oceanic circulations and the solar radiation were favourable.

Applying this to the Permo-Carboniferous epoch, and consulting the reconstruction formerly given by me³, it will be discovered that no part of the great hypothetical ice-cap need have been more than some 1,700 miles from the nearest ocean, the existence of which is indicated by marine deposits, in several cases intercalated in or immediately succeeding the glacials, as mentioned by Prof. Coleman. Such strata were clearly laid down in bays and gulfs penetrating into a low-lying continent or assembly of continents.

There is positive evidence of the successive overlapping of ice-bodies, while it is furthermore unlikely that the entire territories known to have been affected were ever completely ice-covered at one and the same time—precisely as in the case of the Pleistocene glaciation. It is logical to presume—and the geological evidence is in agreement therewith—that the ice started collecting at isolated points, that such bodies increased in size and that the weighting of the continent by snow helped to cause depression and invasion by the sea, with rapid expansion of the ice-caps and their ultimate coalescence. It is unnecessary to suppose that such a continent was pushed polewards for each glaciation and pulled back for each interglacial phase. The observed phenomena could more intelligently be explained by fluctuations in solar radiation, etc. There is internal evidence also to suggest that the Permian coals of Gondwana, unlike the Carboniferous seams of the northern hemisphere, were cold climate interglacial or post-glacial accumulations.

In his monograph², Prof. Coleman has deplored not being able to explain the distribution of past glacial deposits, which suggests that he must have overlooked some vital factor. Others too have failed to interpret such glacial phenomena in terms of existing geographical and meteorological environments.

The hypothesis of drift endeavours to explain the Permo-Carboniferous glacials as formed around the south pole of that period, upon a reassembled

Gondwana, though not centrally thereon, and with adequate oceanic areas at hand for the required evaporation. The principle can furthermore be invoked to account for the still older glacials that, significantly, lie within the very region affected during the Palaeozoic, of which at least five groups of widely different ages are known in southern Africa alone.

Instead of contending that the Permo-Carboniferous glacials could not have been developed upon a single land-mass, as he does, I feel it would be more helpful if Prof. Coleman could show how they could have been laid down at all in the several widely-parted areas in the positions and latitudes which they occupy to-day.

In the various orogenic zones of the earth, for example, in the Appalachian region, hundreds of miles of horizontal sediments have been compressed laterally into a fraction of the space originally occupied by them. When a convincing explanation can be given of how such could have happened, and also what material now fills the corresponding gap in the earth's circumference whence the crumpled-up strata came, an answer should be forthcoming for the elusive mechanism of continental drift.

Scattering of Radio Waves in Polar Regions

THE interesting letter by Harang and Stoffregen¹, concerning ionospheric radio wave reflections at Tromsø, prompts the recollection of some observations made by us at the same observatory during the Second International Polar Year, 1932-33, on a type of radio echo which seems peculiar to polar regions.

A reproduction of the radio echo delineation observed at Tromsø using 4.0 Mc./s. waves at 1600 M.E.T. on July 31, 1933, is shown in the

accompanying figure. (In this figure the cathode ray spot provides a time-scale trace by moving around the depicted ellipse in a right-handed fashion.) It will be seen that in addition to echoes from Regions E and F, there is also a distorted echo S with a delay time of 7.5-9.5 milli-seconds, indicating reflection or scattering at a distance of 1,125-1,425 km. from the sending and receiving stations. The special interest of the record, however, arises from the fact that it is

possible in this case to decide whether the echo is due to reflection at vertical incidence or to sideways scattering. Since both first and second order reflections from Region *F* are present, we know that the frequency used is less than the critical penetration value for that region. Moreover, since Region *F* is known to be thick, when measured in terms of a vacuum wave-length, we know that there can only be negligible penetration of the region for frequencies less than the critical value. We can therefore conclude that the echo *S* is due to sideways scattering from some complex ionized centre situated in or below the normal Region *F*, and is not due to reflection from very great heights. In this connexion it may be recalled that Appleton and Piddington³ have shown that the principal scattering centres of the ionosphere are situated at levels between 80 km. and 160 km. above the ground.

Electric Charge on Soft Hail

IN the course of measurements of the electric current carried down to the earth by precipitation, there have occurred occasions when the results are considered worthy of attention.

On December 19, 1938, during a sharp shower of soft hail (grape), from cumulo-nimbus clouds, the charge brought down to an area of about 1 metre square in the ten-minute period 12.56–13.06 amounted to more than -4.4×10^{-8} coulombs, corresponding to an average current of more than -7.3×10^{-10} amp./cm.². This appears to be a larger precipitation current than has ever been previously observed. Over an area of 1 km.² this amounts to a charge of -44 coulombs in the ten minutes, which may be compared with a value of $+35$ coulombs for the fine-weather current for a whole year, as obtained from the results of Sorase¹.

This particular occasion gave a larger current than in other cases, but there also occurred, on the same and the following day, average currents over a ten-minute period of $+3.8$, $+1.1$, -0.8 (twice), $+0.7$ and -0.7 , as well as many others greater than ± 0.1 , the unit in each case being 10^{-10} amp./cm.²; in addition, there were occasions when the currents were not recorded, and these may have been large currents. In the parts of the earth where such showers are frequent, particularly at high altitudes and in high latitudes, it is probable that the charges brought down to the earth will be very considerable, and will be of much importance in the discussion of the maintenance of the negative charge on the earth's surface. It is therefore desirable that similar measurements should be carried out at such places, if opportunity offers.

Catalytic Exchange of Deuterium and Hydrogen in Hydrocarbons

CATALYTIC interchanges of hydrogen atoms between molecular hydrogen and hydrocarbons of the type $\text{RH} + \text{D}_2 = \text{RD} + \text{HD}$ have already been repeatedly observed¹⁻⁴. The following instances of catalytic exchange seem of special interest as they proceed rather rapidly under mild experimental conditions and give important indications as to the mechanism of exchange reactions in general.

If a mixture of deuterium and cyclohexane or *n*-hexane vapour is brought into contact with a platinized platinum foil (10 mm. $\times$ 10 mm.)⁵, an interchange of hydrogen atoms takes place at the following speeds:

Reaction volume, 78 c.c.; total pressure, 80 mm. mercury.		
Mixture	Temperature ($^{\circ}\text{C}$)	Half-period of exchange (min.)
Cyclohexane-deuterium	57	150
	66	23
	97	11
Hexane-deuterium	55	33
	82	11
	124	3

In each case, the exchange can be followed up until the exchange equilibrium is completely established. Under the given experimental conditions, no chemical change other than exchange occurs. In the case of the cyclohexane, it can be shown that the establishment of the equilibrium $\text{C}_6\text{H}_{12} = \text{C}_6\text{H}_6 + 3\text{H}_2$ cannot account for the observed exchange. The mechanism of these exchange reactions seems to involve the detachment of one hydrogen atom from the hydrocarbon, as was suggested for the exchange reactions of ethylene and benzene². It is most probable that the same mechanism is operative in the exchange reactions of all kinds of saturated and unsaturated hydrocarbons in general.

Finally, it may be mentioned that the present experiments offer a convenient method for the preparation of deuterated hydrocarbons.

Availability of Phosphorus in Rice

A LARGE proportion of the phosphorus present in rice, as in all other cereals, exists as the poorly utilizable phytin¹, and to this fact is ascribed the rachitogenic action of cereal diets².

In investigations on the nutritive value of rice varieties³, I observed that the average growth-rates induced in groups of young rats fed solely on the different rice varieties, together with adequate supplements of all the vitamins, were essentially related to their contents of proteins and minerals, particularly phosphorus. In the following test, an attempt was made to determine the growth-promoting qualities of the phosphorus compounds in two varieties of rice

the chemical composition of which, in percentages, is given below :

Variety	Moisture	Protein (N x 6.25)	Bitter ex- tractives	Carbohy- drates	Total minerals	P ₂ O ₅	CaO
Adt. 6	11.2	7.70	2.24	74.8	1.64	1.14	0.09
Adt. 11	12.4	5.77	2.23	77.7	1.23	0.61	0.08

The powdered rice was used for feeding, but in one case (Adt. 11) the rice flour was intimately mixed with 2 per cent of a preparation of rice protein (purity = 94 per cent) so that the protein contents of the two feeds were nearly the same. The rices were then mixed with 5 per cent of a phosphate-free salt mixture composed of calcium lactate (150 parts), magnesium sulphate (30 parts), ferric citrate (12 parts), sodium chloride (10 parts) and potassium chloride (10 parts).

Groups of four young rats were fed on the two diets thus prepared, together with the same supplements of cod liver oil and 'Marmite' extract. The experiment was continued for a period of six weeks. The average weekly growth-rates (increase in weight in grams) were as follows :

Rice	1	2	3	4	5	6
Adt. 6	13.2	12.6	10.8	8.4	7.0	6.2
Adt. 11	9.6	10.4	8.4	6.8	5.4	5.0

In spite of the protein contents having been adjusted to the same level in both the diets, there is observed a definite difference in growth-rate due to the two varieties of rice. This is evidently traceable to the differences in the mineral contents of the grams. Since the salt mixture used contained enough supplements of all the minerals excepting phosphorus, it is reasonable to assume that the better growth induced by Adt. 6 is due to its containing more (about 1.9 times) phosphorus than Adt. 11.

The presence of a phytase in the intestines of the rat⁴ and its possible significance in rendering available the phytin to the animal organism have been indicated, but the evidence is yet inconclusive⁵. The present note would point to the need for further work in this direction.

Self-Sterility in *Oenothera*

Oenothera missouriensis is a species with flowers of maximum size. It, and certain related species¹, extend from Missouri through Oklahoma, Texas and adjacent regions in the western States. It differs from ordinary species in being perennial and in developing enormous wings on the fruits. The seeds are also very much larger and fewer. Because of these characters it has been placed by some in a

separate genus, *Megapterium*. Unlike most of the true *Oenotheras*, which have developed catenation of their chromosomes in meiosis, *O. missouriensis* was found to have seven free pairs².

For several years a plant has been grown at the Courtauld Laboratory, Regent's Park, and as it bore

no fruits nor seeds efforts have been made every year to obtain seeds by selfing the flowers by hand. Not a single flower, however, set seed, whether hand pollinated or not, although a large number of flowers bloomed every year. This finally led to the conclusion that the species was probably self-sterile. Last summer this was confirmed by pollinating the flowers from a strain grown at the Merton Laboratory. Four flowers were cross-pollinated and they all showed a good setting of seeds.

Some strains of the species have round red spots on the sepals, and this was true of the Regent's Park plant, while the sepals of the plant from Merton were devoid of the red spots. Certain other differences were also observed, the inheritance of which will be studied.

It thus appears that while the subgenus *Onagra* has developed chromosome catenation as a mechanism for maintaining a heterozygous condition in its species, the subgenus *Megapterium* has produced the same result by developing a mechanism of self-sterility.

Induction of Polyploidy in Chilli (*Capsicum annum* L.) by Colchicine

THE discovery by Blakelee¹ in 1937 that treatment with colchicine induces doubling of chromosomes in plant cells, leading to the production of polyploids, is of practical importance to the breeder who is faced with the problem of sterility in hybrids from wide crosses, arising from the different material constitution of the chromosomes of the parents. Except in those cases where sexual propagation made possible their utilization, it has not hitherto been possible to take full advantage of such crosses. The results of experiments so far carried out with colchicine, although mostly of a preliminary nature, have raised hopes of producing vigorous fertile forms from sterile hybrids, and several workers, notably Dermen² (1938), Nebel and Ruttle³ (1938), Levan⁴ (1938) and Kostoff⁵ (1938), have repeated the experiments of Blakelee and reported favourably regarding the efficacy of this alkaloid in producing polyploids.

The study of the effects of this chemical on several economic species of plants has been undertaken and a preliminary account of results obtained with chilli is here reported. Seeds were immersed in 0.05 per cent, 0.1 per cent, 0.2 per cent and 0.4 per cent solutions of colchicine in water for 1, 2, 4, 6 and 8 days and planted in the field with controls. While the control plants were normal in growth and flowered almost at the same time, some of the treated plants showed various degrees of abnormality of growth in the early stages such as roughening and

thickening of the leaves, fasciation of stems and other vegetative organs and doubling of flowers. These were generally slow growing, developed broad and succulent leaves and flowered later than the controls and had varying percentages of sterile pollen, the fertile pollen being nearly double the volume of the pollen of normal plants. The seed setting was considerably reduced in such plants as compared with the normal plants. The abnormal plants on examination by aceto-carminic smears of pollen mother cells proved to be tetraploids. Polyploids of higher order than tetraploids was not observed although 2n and 4n tissue was found to occur in the same plant in some cases. The accompanying table gives the number of diploids and tetraploids occurring in the different treatments.

Strength of aqueous solution of colchicine	0.05 per cent			0.1 per cent			0.2 per cent			0.4 per cent		
Period of immersion of seed in colchicine	Diploids	Polyploids	Per cent of Polyploids	Diploids	Polyploids	Per cent of Polyploids	Diploids	Polyploids	Per cent of Polyploids	Diploids	Polyploids	Per cent of Polyploids
1 day ..	27	2	6.9	20	1	4.8	4	11	73.3	4	6	60.0
2 days ..	19	4	17.4	20	3	15.0	5	11	68.8	2	5	71.4
4 days ..	5	3	37.5	5	2	29.6	1	4	80.0	1	—	—
6 days ..	16	3	15.8	8	4	33.3	2	2	50.0	4	4	50.0
8 days ..	9	4	30.8	4	6	60.0	7	1	12.5	2	1	33.3

Besides the tetraploids, one triploid was also identified among the treated plants. It is at present not possible to say if this arose spontaneously or as a result of the treatment. In addition to polyploids, we have isolated a few diploids among the treated plants showing meiotic irregularities leading to the formation of sterile pollen. A further account of these and the tetraploids will be reported elsewhere.

Period of Gestation of *Loris*

In a recent communication¹, Dr. W. C. O. Hill suggests from certain evidence that "the gestation period [in *Loris*] is somewhere in the neighbourhood of six months". The following history of a pair of lorises will be of interest, and confirms Dr. Hill's opinion.

Lorises had not been found in Ceylon above about 3,000 ft., where a race occurs differing from the common low-country loris in a few details: it has been named *L. tardigradus grandis*. In May 1937, Mr. A. O. Tutien-Nolthenius sent me two large lorises which had been caught on his estate near the Horton Plains at a height of between 5,000 ft. and 6,000 ft. They are robustly built and have very thick and long fur, and may be considered an extreme type of *L. t. grandis*. These were kept in a large cage (8 ft. square), and in June I introduced into the cage for the purpose of comparison a male which had been caught at 3,000 ft. This male happened to be 'in season', and fighting took place between the two males, so that I was obliged to remove the one newly introduced. I noticed the next day that the

high-country male had come 'into season'. It may have been stimulated by the presence of the other male. I am familiar with two sounds made by lorises, the first is a hissing sound made when they are quarrelling or frightened, and the second is a low oall which can be heard from a much greater distance. On the night of June 23, I heard sounds coming from the cage; these so closely resembled mewling that I thought a kitten was in or on the cage, but on investigation I found that the lorises were mating, and both were emitting the mewling sound. They have been carefully watched from that date. The male has not come 'into season' again. On December 14 the female gave birth. Therefore the period of gestation was 174 days, which is about one week short of six calendar months.

The young loris is about the size of a half-grown mouse; and it is carried about clinging to the hair of the mother's abdomen.

The 'Thumb' of the Giant Panda

THAT Mr. Pocock (see *NATURE*, Feb. 4, p. 206) finds the radial sesamoid and the palmar pad that covers it are "capable of only slight movement" in the dead specimen may perhaps be explained in part by the rigidity of the tissues in the undissected cadaver. For most certainly, during the progress of dissection, a very high degree of mobility is demonstrated; and even in the bones themselves, the same fact is attested to in the large, bevelled cartilage-covered joint surface between the scapholunar and the sesamoid.

Moreover, Mr. Pocock overlooks the most interesting facts in this remarkable adaptation—that powerful muscles inserted to the mobile thumb in normal mammals are, in the giant panda, inserted to the mobile sesamoid, while thumb muscles arising from the fixed trapezium in normal mammals are here transferred to the mobile sesamoid. The whole muscular and articular adaptation is towards the end of producing movements of the sesamoid, and of its free mobility there can be no question.

When Mr. Pocock declares the mechanism in the panda to be "exactly comparable to that produced by bringing the tips of the first and second fingers on to the ball of the thumb in the human hand", he is stating an obvious truth; but he seems to overlook the fact that, like the panda's radial sesamoid, the metacarpal of the human thumb is also mobile.

Electrified Motor-Vehicles

WHILE to experience an electric shock from a motor-vehicle appears from a recent note to be unusual in England¹, it is so common in the United States as to call for no comment. An interesting consequence of this phenomenon is to be seen on the San Francisco-Oakland and Golden Gate Bridges, where thousands of cars a day pass the toll gates and where the continuous small shocks suffered by receivers of toll on touching coins handed to them by drivers of cars have proved very unpleasant. Wire brushes standing about one foot high have accordingly been installed immediately before all toll gates so that cars as they approach are relieved of their accumulated charges. In at least one toll station in this country a jet of water is sprayed on the wheels of approaching cars for the same purpose.

In many States and municipalities there is a law

compelling vehicles carrying petrol and similar inflammable products to drag chain behind them in order to discharge continuously any electrostatic charge of the vehicle. On a dark night I have seen a continuous glow coming from such chains dragging over asphalt roads, quite different in appearance from sparks which might be produced by striking stones. In the State of Massachusetts, however, I understand there is a law prohibiting drag chains on the grounds that the frictional or electrical sparks so generated might ignite a leaky truck.

Points from Foregoing Letters

FOLLOWING upon Hahn and Strassmann's observation that isotopes of barium are probably formed when uranium is bombarded with neutrons, Prof. Lise Meitner and Dr. O. R. Frisch discuss a new type of nuclear reaction in which a heavy atomic nucleus after taking up a neutron splits into two roughly equal nuclei, very much as a drop of water breaks into two when its size is large and its surface tension is low. In the case of uranium, if one of the new atoms formed is barium the other will be krypton. Thorium apparently breaks up into barium and lanthanum isotopes.

A new thermostatic arrangement for keeping apparatus at constant temperature within 0.002° C. without the necessity of careful insulation or surrounding with a circulating liquid, is described by Prof. T. H. Laby and V. D. Hopper.

Sir Joseph Larmor points out that the tensor scheme of relativity cannot by itself deal with the relation of an asymmetrical object to its mirror image. To be effective for this purpose, the mobile measuring rod of Einstein would have to possess a screw structure essential to it.

By applying a suitable canonical transformation to a system consisting of nuclear particles and a meson field, and by assuming an interaction between the meson field and electrons and neutrinos, Dr. O. Møller and Prof. L. Rosenfeld arrive at a transformed Hamiltonian containing a term which gives the probabilities of beta-disintegration processes. The introduction of a pseudoscalar wave function, in addition to the four-vector one, offers the possibility of a better adaptation to the experimental results.

Dr. Harold Jeffreys, in reply to Dr. W. Edwards Deming, maintains that the notion of reasonable degree of belief is implicit in every application of the theory of probability, and that the frequency definition, though designed to avoid this notion, in fact fails to do so in actual application.

Commenting on Prof. Coleman's contention that the late Palaeozoic glacials of the southern hemisphere would have necessitated the presence of relatively warm seas in the neighbourhood, Dr. A. L. du Toit states that conditions of oceanic and atmospheric circulation and solar radiation are more important for the formation of an extensive ice-cap than nearness to warm water, and that the hypothesis of a

south polar drift of the Permo-Carboniferous Gondwanaland is not invalidated.

Prof. E. V. Appleton and R. Naismith describe the reception of a medium-delay radio echo at Tromsø during the International Polar Year 1932-33, under ionospheric conditions such that it was possible to interpret the results as due to lateral scattering from a complex ionized centre at a considerable distance, and not to reflection at a very great height above the ground.

Dr. J. A. Chalmers and E. W. R. Little report a measurement of an average precipitation current for a period of ten minutes of more than -7.3×10^{-12} amp./cm.², during a shower of soft hail. This exceeds the vertical fine-weather current for a whole year.

Prof. L. Farkas and A. Farkas find a fairly rapid rate of exchange between the hydrogen atoms in the molecule of hexane (or cyclohexane) and deuterium, when a gaseous mixture of the two is brought in contact with platinized platinum foil.

In experiments on the growth of young rats fed on two varieties of rice, adjusted to the same protein content, but differing widely in regard to their phosphorus contents, Dr. A. Sreenivasan finds that the growth rate is greater with the variety of rice containing the larger percentage of phosphorus.

A variety of *Oenothera missouriensis* grown at the Courtauld Laboratory, Regent's Park, London, has been found to be sterile when self-pollinated. The plant has seven free pairs of chromosomes, and Prof. R. R. Gates suggests that it has developed a mechanism of self-sterility in order to maintain a heterozygous condition.

By immersing seeds of chilli (*Capsicum annum*) in solutions of colchicine of various concentrations, Drs. B. P. Pal and Dr. S. Ramanujam have obtained plants with increased number of chromosomes (tetraploids and one triploid) showing abnormality of growth (thicker leaves, fasciation of stem, doubling of flowers).

Dr. Lucius Nicholls records the mating of a pair of lorises in captivity. They had been caught in the hills of Ceylon at a height of between 5,000 ft. and 6,000 ft. They made a curious mewing sound whilst mating. A living young one was born 174 days after mating had taken place.

Research Items

Diet of Serbian Gypsies

IN Serbia it is known that gypsies feed on carrion, and a number of instances of their addiction to the flesh of animals, which have not been slain for food, but have died a natural death or from disease, have been collected by Dr. Alexander Petrovič in a further contribution to his studies of the gypsies of Serbia (*J. Gypsy Lore Soc.*, Ser. 3, 18, 1; 1939). This is a matter of preference, as it occurs even among the more well-to-do. Mirijevo, a village near Belgrade, where there are some twenty gypsy families whose material condition is comparatively good, is renowned for the fact that its gypsies eat carrion. When a peasant has a sow or hog or an ox that has died of some disease, he buries it in a piece of ground near the road. Someone will then inform the gypsies of the fact, and they will pay a small sum for the information. Then at night two or three will go to the spot indicated, dig up the carcass, and carry it home. At Rakovica, also near Belgrade, when there was a serious pestilence among the sheep in 1937 the peasants were at their wits' end to know what they should do with the dead sheep. Some were buried, others thrown into the fields and meadows. Gypsies from Ripanj, an outlying village, used to come at night, dig up the carcasses, and carry them away. Dead horses are also dug up and their hides, and sometimes the meat as well, are sold; but a gypsy never eats horseflesh, because the horse is a friend of the gypsies and is considered more or less a member of the family. Some of the poorer gypsies eat carrion meat without special preparation; but others prepare it by washing, soaking with nettles or garlic, and boiling until the smell has gone. Sedentary gypsies eat carrion meat only when with gypsies who prepare it in this way. It is then said, however, to be tasteless; while those who express preference for the flesh of animals that have died, say that it is on account of its flavour, which is superior to that of slain meat. Whether the sense of smell among gypsies is deficient is neither clear nor easy to ascertain. Their vocabulary, though not decisive one way or the other, suggests that they do not discriminate very decidedly between smells, good or bad.

Race, Religion and Caste in India

IN the course of a study of the racial affiliations of religion and caste in India, Rai Bahadur Sarat Chandra Roy considers the probable contribution to the formation of caste of the Alpine and Mongol racial elements in the population (*Man in India*, 18, 2-3, 1938). One section of the Alpines appears to have entered India by way of the Pamir plateau and the Hindu Kush in the Chalcolithic period. At the present time the modern Asiatic representatives of the race are found in this region in their greatest purity, and the race is also the dominant element in the Khotanese. Neither among these nor among the European Alpines is there found anything resembling the caste system as it is known in India. In central Asia this is not due to the influence of Islam; for the Tajiks of Kashgar, for example, retain customs and beliefs derived from Pre-Islamic times, which are

not approved by Islam. Even class sentiment neither determines occupation nor prevents inter-marriage between different social grades. Among European Alpines, tribal feeling is still, or was until recently, strong among Balloon peoples; and some have bird names. There is also evidence of bird names among the people of Bengal and the Prabhus of Bombay Presidency, who contain a strong brachycephalic element. In comparatively early times Aryans visiting famous places of pilgrimage in Bengal, Gujarat, Anga and Kalinga, presumably of Alpine or pre-Aryan origin, were required to undergo an expiatory ceremony. Although Indian representatives of the Alpines, such as the Bengalis, Gujrātis and Mārāṭas have long adopted the Hindu caste system, they are not as rigid in observance as, for example, the Dravidian Hindus of the south. Buddhism with its doctrine of equality was especially strong in Bengal and among Gujrātis, as also were Vaishnavism and Jainism. The first historical king of Bengal, Gopala Deva, was elected by the people, and the Mārāṭas have an equally democratic spirit. Modern movements for social and religious reform have been initiated and developed for the most part by men of the Indo-Alpine race; but they appear to have contributed little to the formation of the complex caste system.

Growth of Tissues in Vitro

O. A. TROWELL and E. N. WILLMER (*J. Exp. Biol.*, 16, 60; 1939) made tissue extracts from several organs of growing and adult fowls and tested the growth-promoting properties of these extracts on periosteal fibroblasts growing *in vitro*. They found that these properties were most pronounced in brain extract and diminished in the following sequence—thyroid, thymus, testis, ovary, bone-marrow, liver, kidney and muscle extracts. Extracts made from the spleens of adult cocks were far more efficient growth-promoting agents than extracts made from the spleen of young birds. The growth-promoting power of a tissue extract could not always be correlated with the age of the tissue from which the extract was made, with the rate of growth of that tissue or with its nuclear content.

Rat Fleas in Plymouth

R. B. MAYFIELD (*Parasitology*, 30, 314; 1938) investigated the species and numbers of fleas harboured by rats in a certain section of the Plymouth docks, and also examined a few rats from the town of Plymouth. The total number of rats investigated was 83. Of 77 rats caught in the dock premises, 63 were examples of *Rattus norvegicus* and 14 of *Rattus rattus* which were found to harbour three species of fleas, namely, *Nosopsyllus* (*Ceratophyllus*) *fasciatus*, *Xenopsylla cheopis* and *Leptopsylla segnis* (*musculi*). The presence of *Xenopsylla cheopis* was almost entirely confined to a certain grain store. Four specimens of *Rattus norvegicus* and two of *Rattus rattus* were caught in the town of Plymouth and yielded 32 specimens of *Nosopsyllus fasciatus* and 3 of *Leptopsylla segnis* but no *Xenopsylla cheopis*.

Bird Fauna of a Rocky Island

THE aptitude of some animals to make use of the most unpromising conditions is shown by a short account of the birds of Malpelo Island by James Bond and Randolph Meyer de Schauensee (*Proc. Acad. Nat. Sci. Philadelphia*, 90, 155; 1938). The island is a bleak pinnacle of volcanic rock, 330 miles from the mainland of Columbia; the upper plateau presents "one of the most barren, bleak expanses of rock I have ever seen. Not a single plant living or dead was to be found", says one of the authors; the only vegetation the survey revealed was on a steep cliff about 200 ft. high, where there was a moss and a grass growing from the damp crevices. Yet here was found a small fauna of ten species of birds. Most of them were sea-birds, which depended upon the surrounding ocean to supply them with food—a booby, a small colony of frigate birds, a colony of thirty gulls, and two species of terns. But there were waders, ten spotted sandpipers in company with about twenty-five wandering tattlers (*Heteroscolus incanus*), a duck hawk, and more remarkable still, a martin (*Progne* sp.) and barn swallows which were apparently inhabiting a cave. The latter birds must have been subsisting upon some sort of insect life; it would be of great interest to know the complete fauna of this isolated and barren island. The visit was made on February 8, 1937.

Census of Californian Sea-Lions

COMPLAINTS have been made by commercial and sport fishermen that the sea-lions of California cause inordinate damage to fish stocks and to fishing gear, and that the destruction is increasing with a numerical increase in the seal colonies. It was thought possible that the Californian population had been increased on account of the migration northwards of Mexican individuals, following upon the activities of a company engaged there in killing and canning seal flesh for cat and dog food. To test these suppositions, a census of the seal rookeries was carried out between June 18 and 26, 1938 (*California Fish and Game*, 24, 415; 1938). This census did not reveal any great change in the sea-lion population. During the last census, in 1936, Steller's sea-lion (*Eumetopias stelleri*) had a total population of 4,900, in 1938 it was 5,841; while the corresponding figures for the other species, the Californian sea-lion (*Zalophus californianus*) were 2,501 and 2,020. Indeed, the five counts carried out from 1927 to 1938 show that the sea-lions have remained about the same numerical level, for although the trimming hunters have ceased to kill the adult bulls and the State law protects the animals, a good many are still slaughtered annually by 'sportmen' and fishermen. Natural mortality is heavy, not more than 50 per cent of any year's crop of pups reaching the age of one year, while the death-rate amongst adults is also comparatively high; so that the present birth-rate seems about to balance the death-rate. The conclusion of the authors, Paul Bonnot, G. H. Clark and S. Ross Hatton, is that for the present there seems to be no reason for reducing their numbers.

Host Selection in a Chalcid Wasp

D. C. LLOYD, of the Farnham House Laboratory, Imperial Institute of Entomology, describes his attempts to determine those factors that are involved

in the selection of hosts by the chalcid *Ooencyrtus lucanice* (How.) (*Phil. Trans. Roy. Soc., B*, 227, Dec. 1938). He also describes observations made on the distribution of the eggs in a restricted environment (Petri dishes) such as when the chalcid is kept in immediate contact with the host (eggs of the gypsy moth) in which it lays its eggs. It is shown that egg-laying by this parasite is not at random but has reference to the nature of the host available. Usually the female selects unparasitized hosts. If she is forced to superparasitize, she selects those host-eggs containing the youngest parasites. If only parasitized hosts are available the female parasites tend to retain their eggs rather than deposit them. It is concluded that the oviposition response is to a perceptual complex of stimuli which is such that the female insect tends to select those hosts in which the progeny are able to develop.

Post-Glacial History of Fenland Vegetation

A SERIES of sections and bores throughout southern Fenland show a stratigraphical sequence of lower peat, fen clay and upper peat to occur regularly over the entire area. Past ecological and climatic changes reflected in this succession have formed the subject of an investigation by H. Godwin and M. H. Clifford (*Phil. Trans. Roy. Soc., B*, 229; Dec. 1938). Tree remains are abundant in the lower peat. At Woodwalton Fen this peat formation apparently led to the destruction of pre-existing oakwoods on clay giving rise to, at first, open water or alder brushwood, passing gradually into drier fen woods with oak, birch and pine. The clay bed separating the peats is shown by foraminiferal and diatom analysis to have been laid down in brackish water and hence represents a marine transgression. A freshwater phase developed later with extensive development of *Sphagnum-Eriophorum-Calluna* peat and the formation of raised bogs which were locally submerged later by the formation of meres in which calcareous lake marl was deposited over the acidic *Sphagnum* peat. The correlation of the vegetation phases with archaeological and climatic horizons leads the authors to date the general formation of peat in the fens in the Atlantic period. They became wooded in the Neolithic period and the marine transgression which gave rise to the fen clay occurred at the end of the Neolithic period. The raised bogs were developed during the Bronze and Iron Ages. A second marine transgression occurred in Romano-British times. This gave rise to a layer of semi-marine silt which overlies the upper peat on the seaward side of the fens and along the courses of the estuaries. There were human settlements upon the silt whilst it was forming, and its present surface shows the remains of dense occupation. The great meres of the Fenland probably formed either in the Iron Age or the Romano-British period.

Greenland Plankton

THE Godthaab Expedition visited the waters west of Greenland in 1928, and extensive plankton samples were taken and associated with hydrographic work. The collector, Gunnar Seidenfaden, gives an account of the work of collecting, and his experience of the inadequacies of his equipment should be of value for guidance of future expeditions. The material collected has been worked over and described by

Jul. Grøntved, who has collaborated with Seidenfaden in the account of the distribution of plankton (*Meddelelser om Grønland*, 82; 1938). Previous records of plankton from 1850 onwards for the region are discussed and incorporated in the distribution maps for the species, now greatly extended through this expedition, especially in the more northern waters, and this volume forms an extremely useful basis, upon which more detailed knowledge may be built up. The samples include surface collections, and a considerable number of depth samples, especially down to about 100 m.; the species fall mainly into the groups Diatomae, Peridinae, Flagellate, Ciliatae. (Chlorophyceae were not observed in the material.) The Grinnell Expedition, 1850-51, collected a sample of 'red snow', and it is of interest that this appears to have been from Crimson Cliff, near Cape York, which again on this present expedition showed the same phenomenon. This well-known locality for 'red snow' is due to perennating snow flats, near bird-cliffs, which supply the nutriment for the organism.

Moisture in Wood

A BROCHURE entitled "Recent Work on Moisture in Wood" by W. W. Barkas, issued for the Forest Products Research Laboratory (H.M. Stationery Office, 1938), summarizes the results of recent research undertaken by the Physics Section. The objects of the study were the mode of retention of water by wood, and the part which this water plays in determining the strength and shrinkage of the material. The main conclusions arrived at are (1) the differentiation between the molecular and capillary water held in the cell wall, (2) the demonstration that the water in the cell cavities cannot be sharply differentiated from the capillary water in the cell walls, (3) the proof that strength, shrinkage and vapour pressure changes begin in the wood as soon as it is dried below the waterlogged moisture content, (4) the evidence put forward that wood reacts identically under externally applied loads and under internal shrinkage forces.

Clover Creek Earthquake of July 15, 1938

THIS earthquake was worthy of particular study by H. Landsberg (*Bull. Seis. Soc. Amer.*, 28, No. 4, Oct. 1938) since earthquakes in the Appalachian region of the United States are singularly infrequent. The shock occurred at 5.45 p.m. E.S.T. (22.45 G.C.T.) in Pennsylvania in an area known as Morrison's Cove, a limestone valley between the Tussey Mountains in the east and the Dunning, Short, Loop, and Look Mountains in the west; in the north the boundary is the Juniata River. The shock was not recorded by seismographs and was probably tectonic in origin, though a 'cave-in' is not an impossible hypothesis. From macroseismic evidence collected by the author and the U.S. Coast and Geodetic Survey, the author was able to construct a map and indicate intensities on the modified Mercalli scale, thus making the epicentre known. For the purpose of estimating the focal depth, H. Neuberger (*ibid.*, p. 259) developed the new formula

$$h = \frac{sR_n^2}{4.6 \log \frac{I_0}{I_n}} - \frac{1.15}{s} \log \frac{I_c}{I_n}$$

where h is the depth of focus in kilometres; s an absorption coefficient; R_n the radius of an area within an isoseist n ; I_0 the Mercalli intensity of the shock in the epicentre; I_n the Mercalli intensity at the isoseist n . Microseismically in the district in question $S = 0.1$, and hence the focal depth was between 0 and 7.5 km.

Oxidation of Carbon Disulphide

IN A study of the non-explosive catalytic oxidation of carbon disulphide vapour in dilute mixture with air, R. H. Griffith and S. G. Hill (*J. Chem. Soc.*, 2037; 1938) made the interesting observation that at about 140° in the glass tube oxidation occurred with simultaneous production of ozone. This is probably due to the presence of atomic oxygen. The yield is fairly small, about 0.5 mgm. of ozone per hour with 65 mgm. of carbon disulphide; but the ozone can be detected by the smell and gives characteristic reactions. This homogeneous reaction is difficult to suppress, but this can be done by adding small amounts of ethylene, when the heterogeneous reaction with nickel sulphide as catalyst can be followed and is found to be of zero order with respect to carbon disulphide. Carbonyl sulphide (COS) was also studied and was found not to undergo homogeneous oxidation so readily and no difficulty was found in following the heterogeneous reaction alone, which was found to be of the first order with respect to carbonyl sulphide but to be retarded by sulphur dioxide. The same authors have previously (*J. Chem. Soc.*, 717; 1938) described the preparation of the catalyst of nickel subsulphide, Ni_3S_2 , from finely divided metallic nickel by the action of carbon disulphide vapour carried in nitrogen at 350°, and have investigated its use in the catalytic hydrogenation of carbon disulphide, carbonyl sulphide, mercaptan and sulphur dioxide, the work being extended by B. Crawley and R. H. Griffith (*J. Chem. Soc.*, 720; 1938).

Nuclear Physics

THE issue of the *Review of Scientific Instruments* of December 1938 devotes eighteen pages of its Physics Forum to a review of progress during the past year by T. H. Osgood of the University of Toledo, Ohio. In the section devoted to nuclear physics the author shows how the study of the products of the bombardment of elements by fast neutrons has led to the discovery of isomeric forms of the same nucleus and he points out the value of the "evaporation" theory of the nucleus, according to which an energetic particle injected into the nucleus shares its energy rapidly amongst the components of the nucleus, which remains in an excited state until a chance accession of energy by a particle leads to its evaporation from the nucleus. Progress in mapping energy-levels has been facilitated by the study of resonance effects when the injected particle has some particular energy. The production of controlled beams of particles has been assisted by placing the electrostatic generators in air at 6 or 7 atmospheres and in this way producing several million volts in a small space. Important results are expected from the new method of producing slow neutrons by the intermittent action of cyclotrons, particularly when the number of instruments is increased by the completion of those now under construction in various centres.

Isotopes of the Alkaline Earth Metals from Uranium

DURING the last two years, the bombardment of uranium by neutrons has led to some striking results, due primarily to the combined efforts of Prof. O. Hahn, L. Meitner and F. Strassmann, working in the Kaiser Wilhelm Institute of Chemistry in Berlin-Dahlem. In addition to *three* artificial isotopes of uranium, they have succeeded in establishing the existence of *six* trans-uranium elements of atomic numbers 93-98, and the existence of a seventh trans-uranium element (half-value period = 60 days) is indicated.

In similar experiments, I. Curie and P. Savitch obtained evidence of the production of a substance with a half-value period of $3\frac{1}{2}$ hours. The identity of this substance is uncertain, and although the authors have considered several possibilities, none of them is very satisfactory. Recent experiments on the chemical properties of the trans-uranium elements have led O. Hahn and F. Strassmann (*Naturwissenschaften*, 26, 755, Nov. 18, 1938; and 27, 11, Jan. 6, 1939) to look for this substance (half-value period = $3\frac{1}{2}$ hours), and they have been successful in obtaining it by the same methods as those used by the French workers. Their investigations have led to remarkable results which are summarized in what follows.

The bombardment of uranium with neutrons apparently resulted in the production of *four isomeric isotopes of 'radium'*, which must have arisen by two successive α -ray transformations via thorium. These four 'radium' isotopes emit β -rays and yield four isomeric isotopes of 'actinium', which, in their turn, by further emission of β -rays, presumably give rise to four isotopes of 'thorium', but details of these last products are still incompletely known. The results so far obtained may be represented provisionally by the following scheme, in which the nature of the radiations emitted and the revised half-value periods of the new products are indicated.

Should this scheme adequately represent the facts, these twelve new substances should have atomic weights of value 231, and since a natural thorium isotope (UY) of atomic weight 231 and half-value period 25 hours is already known, it will be of interest to investigate whether one of the four 'thorium' isotopes is identical with UY.

Hahn and Strassmann believe that the substance found by Curie and Savitch is a mixture of the above-mentioned isotopes, each of which has been individually detected and chemically examined. Moreover, the properties of such a mixture would agree with those of the substance detected by the latter authors, who suspect that their substance also contains others of longer life, but of unknown genesis.

An interesting feature of this work is that the production of the new isotopes is enhanced by the use of *slow* neutrons, and the α -particle disintegrations indicated in the earlier stages of the process are believed to be the first instances of α -particle emission effected by *slow* neutrons. It is, of course, possible that the quadruplicity of isotopes resulting from the bombardment of uranium by neutrons takes place in ${}^{238}_{92}\text{U}$, as in the case of the trans-uranium elements, and the intermediate 'thorium' isotope ${}^{235}_{90}\text{Th}$ may also possess four half-value periods.

In the second of their publications mentioned above, Hahn and Strassmann give particulars of the chemical methods employed in establishing their results, as well as a number of activity curves from which some of the half-value periods have been derived. In order to establish beyond question the chemical nature of the products they have designated 'radium' isotopes, which were separated with barium, the authors carried out fractional crystallizations and precipitations with the active barium salts, by the method used for altering the concentration of radium in salts of barium containing radium.

As is well known, crystals richer in radium can be obtained by fractional crystallization of the chloride, bromide or chromate of barium, when it contains radium. In experiments on these lines, carried out by Hahn and Strassmann with their active barium preparations from which disintegration products had been removed, negative results were always obtained, that is, the activity was uniformly distributed amongst the various barium fractions, whereas control experiments with barium containing the radium isotopes ThX and MeTh_1 yielded results conforming to those obtained when the barium contains ordinary radium. In a further experiment, in which ' Ra_{IV} ' and MeTh_1 were mixed with barium and then subjected to fractional crystallization, only the MeTh_1 was concentrated in the process.

The authors conclude from these results that their 'radium' isotopes have the properties of barium, and that, from the chemical point of view, other elements being excluded, these active substances must be regarded as consisting not of radium but of *barium*. This conclusion has been confirmed by further indicator experiments, according to a personal communication from one of the authors (O.H.).

Hahn and Strassmann have also subjected a mixture of their ' Ac_I ' and the actinium isotope MeTh_1 with lanthanum oxalate to fractionation from a nitric acid solution. At the end of the process a gain in concentration of MeTh_1 was achieved, but no increase in the concentration of ' Ac_I ' was noted. From this they conclude that the substances generated by β -ray emission from their alkaline-earth products are not isotopes of actinium, a conclusion which agrees with that of Curie and Savitch for their composite product of half-value period $3\frac{1}{2}$ hours. In all probability they will prove to be isotopes of *lanthanum*. The products designated 'Th' in the above scheme of disintegration, which constitute the final members of the series

derived from the 'Ac-La' preparations, have not yet been tested for their identity with cerium.

On the strength of the chemical evidence, it is difficult to avoid the conclusion that the elements denoted by the symbol 'Ba' in the above-mentioned disintegration scheme should in reality be designated 'Ba', and so far as the evidence has gone it seems

probable that the succeeding elements 'Ac' and 'Th' will prove to be 'La' and 'Ce' respectively. It is as though, at some stage in the process resulting from the bombardment of uranium by neutrons, a 'collapse' of the nucleus occurs, giving rise to the four active isomeric alkaline-earth elements and the succeeding 'lanthanum' and 'cerium' products. The investigations are being continued. R. W. L.

Subspecies and Varieties

A DISCUSSION dealing with subspecies and varieties was held at the meeting of the Linnean Society on February 2. This discussion had been arranged at the request of the Association for the Study of Systematics in Relation to General Biology in order to obtain information as to the views and principles governing the practice of systematists in various groups of animals and plants. It was apparent from the discussion that systematists are generally dissatisfied with the existing state of affairs. As was to be expected, little or no attention is paid to infra-specific categories in the less-known groups of both plant and animal kingdoms; but where the broader taxonomic outlines are well understood there is considerable divergence in systematic practices according to the amount of genetical, cytological and ecological work that has been done. In vertebrates, only a single infra-specific category, the 'subspecies', is generally recognized, but in entomology and botany there are others. How many there may be and their status in the taxonomic scheme are matters of dispute, and there is a disturbing confusion in the terminology applied to them. In this connexion, it may be mentioned that the Association is compiling a list of the various terms which have been used. Almost all the speakers stressed the need for more experimental work from the genetical, cytological, physiological and ecological aspects.

In opening the discussion, Mr. M. A. C. Hinton described the practice of mammalogists, who, in recent years, have used the term 'subspecies' to express stages or trends in geographical variation; they are sections of what Dr. Julian Huxley has called 'clines' (NATURE, 142, 219; 1938). One principle generally accepted is that no two races of the same species can ever be found on the same ground, though exceptionally two such forms may meet after very different histories and journeys and continue to exist side by side without fusing. The principle that, unless intergradation can be demonstrated, differences, however trivial, indicate specific separation, has some theoretical support. In practice, however, it has disadvantages, especially in dealing with insular forms, and tends to mask that most interesting and instructive phenomenon, discontinuous distribution.

The definition of subspecies is an essential part of any intensive analysis of the facts of variation and distribution, and is particularly valuable in paleontology, by preventing loose identifications and consequent faulty geological deductions. It is hoped soon to commence large-scale experiments to test the values and permanence of subspecific characters and to obtain more definite information on subjects concerning which surmise alone is at present possible.

Dr. W. B. Turrill emphasized that all taxonomic categories are matters of scientific convenience based on abstractions from a continuous evolution. He recognizes that for little-known floras it is undesirable to analyse below the species level; but urged that in relatively well-studied floras the need is for intensive studies of infra-specific variation from every angle. His own researches have led him to the conclusion that taxonomic categories intergrade completely. He suggested that the term 'variety' should be used for every phenotype which is the expression of a different genotype, and that the term subspecies should be used only when a species is in process of breaking up into new ones. Names should be given to infra-specific groups only to serve some definite purpose, and in highly polymorphic species symbols might be used instead. Apomicts should receive distinct treatment.

Mr. A. J. Wilmott pointed out that confusion results from using the words species, subspecies and variety both for categories of variation in Nature and groups of different rank in the nomenclatural system. He suggested that the terms 'binome' and 'trinome' might be substituted for species and subspecies in the nomenclatural sense, leaving the latter free for application to categories of variation. True subspecies are parts of the present time section of a lineage which has become branched by isolation, but the branches of which are not yet completely separated. Varieties, on the other hand, are in a different category, being merely the observed phenotypic effects of separate genes, and not different *kinds* of organisms; they should not be given names under the same system as species and subspecies, but might be designated by symbols.

Mr. J. S. L. Gilmour dealt with the philosophical aspect of the subject and drew a distinction between taxonomic and non-taxonomic infra-specific categories. The former, which might be limited to subspecies, variety, and form, should be based so far as possible on the total attributes of the individuals concerned, while the latter should be based on a selection of attributes chosen for special purposes. Examples of such non-taxonomic categories are Dancer's 'commisum', 'comparium', and 'convivium', based on interfertility data, and useful for investigating the relationship between such data and other attributes, such as morphological differentiation. He urged that this distinction is essential for the proper classification of infra-specific variability.

Mr. H. W. Parker showed that the practice of herpetologists is essentially similar to that of mammalogists. He believes, however, that owing to lack of other data, systematists have laid undue emphasis on geographical considerations, with invidious results. Recognition by trinomials of certain forms to the

exclusion of others equally important, and the inclusion of different grades of infra-specific rank, in the same category is misleading. The traditional methods employed in taxonomy must be supplemented for the study of infra-specific variations, and not until we know more of the categories to be dealt with can a satisfactory scheme of nomenclature be devised.

Dr. B. P. Uvarov expressed his belief that the recognition by entomologists of subspecies, in the sense of geographical races, has been of great practical convenience; it has enabled taxonomists to unite numerous minor forms into large species without losing sight of their individuality. Recent physiological, ecological and genetical work has revealed the existence of races which are indistinguishable by external characters. Between these incipient, deeply seated, internal changes and the appearance of external morphological characters there is probably a time lag; consequently even the smallest external differences, if not irregular and obviously casual, deserve the closest attention as representing quite an advanced stage in variation.

Prof. McClung remarked that the perfect taxonomy has been described as the summation of all biological knowledge; we have obviously not yet reached perfection and the present discontent shows a striving in the right direction.

Mr. C. E. Hubbard said that the terms subspecies and variety are used by systematic botanists to cover every grade from a slight variation in one character to a well-defined species. In the floras of large tropical areas there occur numerous polymorphic species which, in the absence of detailed knowledge, it seems best to lump together and note the polymorphism. Where variations are of economic importance, those that are well defined can

be given binary names with the view of making reference easier.

Prof. F. E. Weiss agreed with the previous speakers that investigations of the taxonomic categories need further biological knowledge, especially genetical. Frequently genetical analysis can establish the status of a taxonomic group when the systematist is in doubt. A good example is seen in the pimpinels; of the two blue forms, one has proved to be a genetically stable species and the other, scarcely distinguishable by any other criteria, merely a mutation of the red species.

Dr. Julian Huxley emphasized that taxonomy deals with natural groups having a real existence. Discussing infra-specific variability, he pointed out that in the gradation between varieties, subspecies and species, the points of stability are more frequent than the intergrading zones. He dealt with various causes of discontinuity and mentioned especially isolation leading to non-adaptive variation, and the production of partial discontinuity by the formation of internally stable gene-complexes. For the description of more or less continuous variation he suggested the use of his 'cline' concept.

Dr. R. Melville pointed out that hybridization is much commoner in plants than in animals and that in certain groups the species can be arranged on an intergrading series corresponding to a 'cline' in Huxley's sense, but with no geographical basis. He suggested that new terminology should be used for forms constituting these series.

Prof. W. Garstang commented on the difficulties of genetical research on animals, and directed attention to the existence of 'clines' in fishes, particularly herrings and mackerel. In some instances, the 'clines' can be correlated with gradual environmental changes.

Interstellar Space

ON May 13, 1938, Prof. Charles Fabry delivered the George Darwin Lecture at the Royal Astronomical Society and dealt with the problem of the nature of the matter which exists in interstellar space (*Mon. Not. Roy. Astro. Soc.*, 98, 9, Supp. No., October 1938). The subject is so vast that it was possible for Prof. Fabry only to review briefly the different methods of investigation and the interpretation which has been placed upon what they reveal. As is well known, the Doppler effect has enabled the interstellar lines to be detected. The displacement of the lines in stellar spectra gives the radial velocity and this should be the same for all lines. If a line gives a velocity which differs from that derived from the displacements of other lines, the discrepancy must be due to matter situated between the star and ourselves—in other words, interstellar matter. In 1904, Hartmann observed the spectrum of δ Orionis, a star of variable radial velocity, and found that the velocity, measured on the hydrogen lines, varied between +133 and -66 km./sec., but the lines of ionized calcium showed a constant velocity of +16 km./sec. This supplied the evidence for the existence of a cloud of ionized calcium between the star and ourselves. It seems remarkable that for fifteen years these

ionized calcium lines were the only ones which were known with any certainty. In 1919, however, Miss Heger established without doubt the existence of neutral lines of sodium, and with improvements in spectroscopic methods more interstellar lines have been discovered. It is interesting to notice that the exploration of the ultra-violet lines of sodium by Adams and Dunham has been rendered possible by the use of aluminized mirrors and of gratings ruled on an aluminized layer. The discovery of other lines which cannot be identified has caused some speculation regarding their origin, and Prof. Fabry conjectures that microscopic crystals, perhaps giving absorption bands at the very low temperature, may be responsible for some of them.

Among some of the interesting results accomplished may be mentioned the estimate of the mean radial velocity of the interstellar matter between the star and ourselves, and it seems that the interstellar gas has the same mean rotation as the galaxy. Quite recently, however, Beals has shown that in some cases it is possible to detect masses of interposed gas which have different velocities. Important developments may be expected in this particular sphere.

It is impossible in the limited space to refer to more than a few of the points dealt with in the lecture.

One matter of some interest may be mentioned in conclusion. Cabannes and Dufay found in the light of the night sky a yellow line which they suspected to be sodium, and during the present year they have been able to show conclusively that sodium lines are present. Bernard showed that this sodium doublet is emitted by the very high layers of the atmosphere, the line being greatly intensified at twilight when the upper atmosphere is illuminated by the sun. What is the origin of this sodium? Does it come from the earth where small crystals of sodium chloride exist

in abundance, or is it interstellar sodium which the earth has picked up in its journey through space? How are the sodium atoms excited? Perhaps solar radiation may be able to produce this excitation, but this, like the other points, cannot be answered at the moment, and we must await future research for light on the subject.

Non-astronomers will find much of the lecture readable and they will be amply repaid for the time spent on studying the numerous matters of interest dealt with by Prof. Fabry.

H. T. de la Beche: Geologist and Business Man

By Dr. F. J. North, National Museum of Wales

FEBRUARY 16, 1839, was an important date in the history of the Geological Survey, for on that day Mr. (as he was then) H. T. de la Beche wrote a letter which eventually resulted in the Survey being changed from a one-man affair, with no settled headquarters, to a great organization with an office in London*. It was something to have persuaded the Government to make a grant of £300 for the purpose of colouring geologically a few sheets of the Ordnance Survey map, but a geological survey of the whole of England and Wales was quite another matter, and, like *Oliver Twist*, de la Beche was continually asking for more—money for instruments, a travelling allowance, and permission to extend the survey into other parts of the country. He was not only able to envisage a National Geological Survey but he had also the courage and perseverance to overcome official inertia in order to establish it.

It is the object of this note to illustrate, by reference to one of his campaigns for the expansion of his work, the kind of man he was and the debt which geology owes to him. It is based upon de la Beche manuscripts deposited by the late Colonel J. I. D. Nicholl in the Geological Department of the National Museum of Wales, and upon some old letter books of the Ordnance Survey, to which, by kind permission of the Director, I was given access.

When the geological mapping which de la Beche had been allowed to undertake in Devon, Cornwall and Somerset was nearing completion, he obtained permission to continue the survey in South Wales, where he found a willing voluntary collaborator in W. E. Logan, then a young man engaged in the copper smelting business, and also received help in the field from one of the Ordnance surveyors, Henry McLauchlan. This help was, however, local and occasional, and arguing that, on the basis of his work in Devon, he could not hope to cover the whole of England and Wales in less than twenty-one years, de la Beche decided to seek permission to secure constant assistance with the view of completing the map in about ten years, and in a letter to Colonel Colby, the director of the Ordnance Survey (February 16, 1839), he wrote:

"It being an object of importance that the Geological Survey should be rendered as efficient as the

money granted for the service will permit, . . . I would respectfully suggest for the consideration of the Honourable Board of Ordnance that I should be permitted to hire such Geological Assistants as I may consider requisite for the proper execution of the work . . . such geological assistants to be chosen by myself and discharged by myself as may in my judgment appear reasonable and proper. . . . I would propose that I should not award any rates of pay exceeding ten shillings per day without special authority from the Honourable Board, and that I should send a quarterly return for the Honourable Board's information, showing the names and rates of pay of the persons so employed."

During the previous five years many letters concerning finance had passed between de la Beche and his employers, and his new application shows that he had profited by his experience. His opening remarks related to efficiency and economy, in his conclusion he disarmed criticism by offering to lay all his cards upon the table, whilst a condition that he knew from experience would be one of vital importance was inconspicuously inserted in the middle.

As usual, the Inspector General of Fortifications was cautious, and he endorsed the application as follows: "I know of no authority for the extensive view here taken of extending the Geological Research beyond the eight sheets of the Ordnance Survey authorized by the Master General's and Board's order of the 2nd May, 1832, and I should beg to submit the expediency of not proceeding . . . until something like an approximate estimate of the whole intended outlay be submitted to Parliament in the usual way."

The result of this endorsement was a letter to Colby stating that "The Master General and the Board are decidedly of opinion that it will never do to go on with this Geological Survey without some distinct rules by which the expense is to be governed. They are desirous of affording Mr. de la Beche every facility, but it must be on some express understanding as to the extent of work to be executed, and the length of time to be occupied. By reference to the original arrangement it will be seen that a most material departure has already taken place from what was then proposed, and . . . what is now asked for will lead to an unlimited expenditure of time and money."

De la Beche was asked to indicate how long the whole work would take, and how much it would cost,

* A brief account of the early history of the Geological Survey was given by Sir John Fleet in "The First Hundred Years of the Geological Survey of Great Britain" (1937), which was reviewed in NATURE of November 27, 1937.

and in reply he explained that it was not possible to estimate "the cost of Geological Surveys and the time necessary for their completion, as until some examination of a given area has been effected no correct idea of the whole expenditure can be formed". The region then under consideration was South Wales, and, he continued, "The coal and iron districts require great care both in scientific and economic points of view, and hence far more time has to be bestowed upon them, than upon most other portions of the country . . . but perhaps thrown in with South Wales generally the whole may be taken at about £1 per square mile".

Colby also replied to the Board, pointing out that the letter which he had received "contains no reply whatever to the original question of Mr. De la Beche being permitted to hire assistants", and stating that he (Colby) had realized the necessity for hiring assistants during the progress of the work in Devonshire.

Careful handling of the situation eventually resulted in an official acknowledgment that it was not possible to foresee and to legislate for every contingency that was likely to arise during the course of a geological survey, and on March 15 it was reported that, "The Master General and Board consider the explanation given to be so far satisfactory as that it limits his labours to the completion of certain parts of the Survey for which the authority of the Treasury has been obtained, and to this he must be confined until the Master General and Board receive further instructions on the subject. With respect to the

expenditure, the only plan . . . will be, from year to year, to take such a sum as may be deemed advisable, upon which point the Master General and Board would from time to time avail themselves of your opinion and so check any extraordinary expense that may be proposed".

De la Beche was quick to act upon the recommendation, for in April he wrote, in a letter to Colby: "I have picked up one very clever hand as an assistant at 7s. per day, a regular good one he is, and I am now on the look out for others". The "regular good one" was David Hiram Williams, who after rendering useful service in South Wales joined the Indian Survey, and his name was given in the "Return of Geological Assistants employed on the Geological Survey of England and Wales", which de la Beche made in June 1839. It will be noted that he wrote of the "Survey of England and Wales", although at the time he had only had authority to work in South Wales.

The "Return" for September 1839 contained two names, for Josiah Rees had been appointed at a salary of five shillings a day, and in December, when de la Beche submitted his estimates for the coming year, he budgeted for four assistants and a total expenditure of £1,400, while in the following year he budgeted for six, and a total expenditure of £1,900—but the question of the possible limit to the duration of the Survey was not raised again, and before the work in South Wales was completed de la Beche was seeking permission to extend his operations into the Forest of Dean!

Hydrogenation of Oils by the Continuous Process

V. T. Athavale and S. K. K. Jatkari have recently carried out a detailed study of hydrogenation of ethyl oleate using nickel-carbonate kieselguhr catalyst (*J. Indian Inst. Sci.*, 21, A, Part 25, 1938) and show a definite advance on previously recorded results. Iodine values, refractive indices and dispersions were determined on a number of samples of hydrogenated ethyl oleate, and results are recorded graphically. Contrary to expectation, iodine values did not vary linearly with refractive index in the initial stages of hydrogenation, but only after the iodine value had fallen by about twenty-five per cent. Comparison of refractive index and dispersion values of samples hydrogenated at different temperatures and with different rates of flow of ethyl oleate over the catalyst showed that dispersions of samples having almost identical refractive indices vary considerably. Similarly, it was found that samples having the same iodine value had dissimilar dispersions, thus indicating the formation of oleic acid during the reaction. A study of the effect of temperature on the velocity of hydrogenation at a fixed rate of flow of ethyl oleate over the catalyst further revealed a marked difference in dispersion values of samples hydrogenated at low temperatures and the conclusion was, therefore, reached that the isomers of oleic acid are formed because of the low activity for hydrogenation of the catalyst at low temperatures.

Interconnected with this research a further series

of experiments were undertaken by the same authors (*J. Indian Inst. Sci.*, 21, A, Part 26, 1938). Earlier work had pointed to the possibility that variations in velocity coefficients of hydrogenation of oils might be due not only to differences in composition of the oils, but equally to differences in the heterogeneity of the catalyst surface. Consequently, a study was undertaken of the velocity coefficients for the hydrogenation of ground-nut oil in the presence of nickel-carbonate-kieselguhr, unsupported nickel-carbonate, nickel-hydroxide-silica gel and nickel-peroxide-kieselguhr catalysts. A comparison was then made with the velocity coefficients of hydrogenation of the same oil over a nickel-wire catalyst. Velocity coefficients (K) were calculated from the equation:

$$K = \frac{2.8}{t} \log \frac{a}{(a-x)};$$

where x is the percentage conversion at a given rate and t is the time of contact. This velocity coefficient was further corrected for the effect of absorption expressed as $K = K^1 (\text{rate})^{\frac{1}{2}}$, where K^1 is the corrected velocity coefficient. By plotting the value K^1 for different samples of oil against temperature, curves showing a maximum at 150° were obtained. This appeared to depend upon the percentage of olein in the oil and its selective hydrogenation at that temperature.

Science News a Century Ago

Researches on the Chemical Equivalents

ON February 14, 1839, Richard Phillips (1778-1851) who from 1839 until his death was chemist and curator of the Museum of Practical Geology, read a paper to the Royal Society entitled "Researches on the Chemical Equivalents of Certain Bodies". The paper was the result of a series of experiments made to test the truth of the theory of Dr. Prout and Dr. Thomson "that all atomic weights are simple multiples of hydrogen", a theory which the late Dr. Turner said was untenable. Turner having adopted the number 108 as the equivalent of silver, Phillips had selected this element as the basis for his inquiry into the equivalent numbers of chlorine and some other elementary gases. From his experiments, the author concluded that no material, and even scarcely any appreciable, error, could arise from considering the equivalent numbers of hydrogen, oxygen, nitrogen and chlorine as being 1, 8, 14 and 36 respectively.

Ehrenberg awarded the Wollaston Medal

AT the anniversary meeting of the Geological Society on February 15, 1839, the Wollaston Medal was handed to the Chevalier Bunsen for transmission to Prof. Christian Gottfried Ehrenberg, of Berlin, to whom it had been awarded for his discoveries respecting fossil Infusoria. "These discoveries," said Dr. Whewell, when handing the medal to Bunsen, "eminently striking and curious to all intelligent persons, are full of the most lively interests for geologists." They were, he added, a just reward of Prof. Ehrenberg's merits, "since he had prepared himself for this success by a profound study of natural history, by practical and scrutinising researches, and by extensive and enterprising travels". In his reply, Bunsen said that the honour accorded "will be deeply felt by the whole literary public of Germany; it will, I trust, form a new link in that intellectual union between the two great and enlightened nations, which have so many objects of warm and deep sympathy; a union which must become every day more and more intimate, and prove productive of the most beneficial consequences, not only for the progress of science in the whole range of human intellect, but for the welfare of humanity at large".

Steel-making in India

DURING the discussion of a paper "On the Differences between the European and Indian Methods of Making Steel", at a meeting of the Asiatic Society on February 16, 1839, Mr. Heath, who had lately returned from the East, described the operations of the natives of India in manufacturing iron and steel. The ore used, he said, was the magnetic oxide of iron combined with quartz in the proportion of fifty-two of oxide to forty-eight of quartz, which occurred in the district of Salem. The ore was prepared by stamping and washing. The furnace was built of clay, charcoal was used as fuel, and the bellows were made of goat skins. The melting took about four hours and the product was hammered into bars. To convert the iron to steel, it was cut into small pieces and placed in crucibles with the dried wood of *Cassia auriculata* and a few green leaves of *Azadirachta indica*.

G. PETIAU: Electromagnetic equations of the theory of the photon.

J. BASSOT: Determination, under pressures of 1-11,000 kgm./cm², of an isotherm of naphthalene tetrahydride passing from the liquid to the solid state.

A. RASKIN: Construction of a high-tension generator with large output. An output of 800 microamp. can be obtained; the voltage, which is limited by local conditions, is 400,000.

G. REMBOUL and F. PERRIER: A peculiarity of air ionized by X-rays. An effect can be detected several hours after the exciting rays are cut off, due apparently to 'large' ions which in number are about a million times fewer than those produced by the same X-rays.

N. KÜRTI, P. LAJTHA and F. SIMON: Adiabatic demagnetization starting from temperatures obtained with solid hydrogen. Using the great magnet of the Academy of Sciences, with a field of 29 kilograms, a temperature of 0.36° K. was obtained in one stage with iron alum. Thus it is possible to dispense with liquid helium for work below 1° K. and hence the equipment required is simplified.

R. FORRER: Relations between the Curie point, orbital moment and crystal lattice.

L. NÉEL: Specific heat and fluctuations of the molecular field.

E. RENCORER: Properties of vitreous phenol phthalein.

L. GROVEN: Contribution to the study of the X-rays emitted in the discharge between external electrodes with maintained waves [of potential].

MILLS, M.-L. DELWAULLE, F. FRANÇOIS and J. WIEMANN: Study of the constitution of solutions of cadmium iodide; complete Raman spectrum of cadmium tetraiodide.

J. CATHALA and J. OLUXEL: Continuation of the spectrophotometric study of the slow hydrolysis of ferric salts.

P. BASTIEN: Influence of pH of acid solutions on the evolution as a function of time of the 'pickle' brittleness of extra soft annealed steel.

J. FARINHAU: Electronic structure of certain copper-aluminium alloys.

J. BOUGAULT, E. CATTELAINE and P. CHARRIER: Nickel amalgams. Nickel can be amalgamated in the presence of nascent hydrogen, which seems to act as a catalyst.

R. CHAUVENET: Combinations of beryllium nitrate and the alkali nitrates.

MILÉ, J. BRIGANDO: Study of ferricyanic, cobalticyanic and chromocyanic acids.

G. COURTOIS: Fusibility of mixtures of pure anhydrous sodium sulphide and sodium sulphate.

A.-A. SANFOURCHE: Magnesium hydroxy-apatite.

G. VAYON, J. CALIN and J. FOUBCHIER: Action of halogen derivatives on magnesium couples.

R. JOUAN: A new method of production of crystals on which physical measurements can be made. A 'seed' crystal is supported in a supersaturated solution on artificial silk gauze carried on an oscillating glass frame.

L. BERTHOIS: Remarks on the origin of tourmaline in sedimentary rocks.

G. CHOUBERT: The Cretaceous of eastern Morocco.

M. THORAL and B. GHEZ: Structure of the western region of the southern slope of the Black Mountains (Aude-Hérault).

R. HUMBERY: Piezometric surface of a sheet of water feeding any number whatever of artesian wells. A theoretical investigation.

J. MOUSSIGOT: Measurements of the conductivity and ionization of the atmosphere in the Alps (work of the Sanatorium des Étudiants de France, and of the chair of therapeutic hydrology and climatology of the Faculty of Medicine of Lyons).

G. GREENET and MME. P. QUENNY: Comparison of electromagnetic seismographs.

H. HUMBERT: An archaic genus of Cucurbitaceae of Madagascar.

G. MANGENOT: Action of colchicine on plant cells. Colchicine immediately prevents cell proliferation though growth continues. This occurs before the appearance of giant nuclei.

A. MICHALSKI and F.-X. SKUPIŃSKI: Ecological researches on *Physarum didermoides* Rost, an endospore myxomycete.

R. SOUBGES: Embryogeny of the Cucurbitaceae; development of the embryo of *Bryonia dioica* Jacq.

J. RIBOUL: General theory of the action of X-rays on biological elements. A revision of Crowther's formula is proposed.

M. PIÉRY, J. ENSELME, C. PESCHIERA and MILÉ, M.-A. NOVA: Effect of the oxygen saturation of arterial blood on the production of lactic acid by striated muscle.

A. BEBEDZKA: Antidiphtheric serotherapy by the cutaneous route. Antidiphtheric serum on the scarified skin of the rabbit is effective, even if applied several hours after penetration of the toxin.

P. LEPESME: Influence of temperature and humidity on the pathogeny of the aspergillosis of Acridians.

Geneva

Physical and Natural History Society (November 17, 1938).

A. PIOTET: Geographical distribution of organisms and the problem of transformism. Studies in the field and laboratory suggest that there is a relationship between geographical separation and racial chromosomal constitution, separation having created germinal differences. This view puts the process of transformism back to early geological times before the continents were separated.

M. PÉREOT: The chromosomes of *Archelix* and of *Alabastrina Alabastrites* Michaud. The chromosome number of *A. Alabastrites* is different from that in the three other species of *Archelix*. It is concluded that the genus *Alabastrina* of Kobelt is artificial, since it contains species related to *Archelix* and others which should be placed in another group.

J.-L. PÉREOT and M. PÉREOT: Chromosomes of five species of *Limnaea*. Chromosome number of *L. auricularia*, *ovata* and *peregra* is 17; that of *L. palustris* and *stagnalis* is 18. This confirms the classical arrangement of the first three species in the subgenus *Radix*. The parallelism between the chromosomal homogeneity and the great resemblance of conchological and anatomical characters is also emphasized.

J.-L. PÉREOT: Is self-fertilization possible in *Eulota fruticosa* Müller? In contrast to a nearly related species, *E. similis simpsoni*, self-fertilization is not possible.

M. L. MISCH and A. J. A. VAN DER WYK: Structure of oxamide. X-ray study of crystallized oxamide shows that it belongs to the triclinic system. Cohesion in the *ac* plane is very great; this accounts for the special physical properties of oxamide.

December 1, 1938.

A. PIOTET: Localization of physiological races of Lepidoptera in the Swiss National Park as a function of altitude and of the flora. The topography and diversity of soils and flora of the Park have localized individuals (of *Nemophila plantaginifolia*) in autonomous stations, where they retain their own physiological and genetic characteristics from year to year.

H. BRANDT and W. SCHUSSEL: Researches on vitamin C during athletic effort. Vitamin C, or more strictly the reducing power of the urine in the dihalophenol-indophenol reaction, may increase or decrease after exertion. The same subject always gives the same reaction, which appears to be a constitutional factor.

December 15, 1938

B. SUZ and E. BRINER: Absorption by benzoic aldehyde in the violet and the near ultra-violet. The coefficient of extinction between 3820 Å. and 4060 Å. has been measured, after elimination by extrapolation of the effect of the benzoic acid always present in small concentration.

P. ROSSIER: Choice of the resistance of the induced circuit in measurements with the ballistic galvanometer. Case of critical damping when the galvanometer deflection is a maximum.

F. CHODAT: Study of chloroplasts by the method of formation of starch *in vivo*. Transformation of starch formed by the chloroplasts, by warming, permits the demonstration of the heterogeneous structure of the chloroplasts; after this treatment they show a series of granulations.

Forthcoming Events

[Meetings marked with an asterisk are open to the public.]

Monday, February 13

UNIVERSITY OF LONDON, at 5.15.—Prof. J. E. Littlewood: "Results in the Theory of Prime Numbers".*

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, at 5.30.—Heath Clark Lectures on "Europe and West Africa: Some Problems of Adjustment" to be given by various lectures (succeeding lectures on February 15, 17, 20, 22 and 24).*

ROYAL SOCIETY OF ARTS, at 8.—Sir Gilbert Morgan, F.R.S.: "Achievements of British Chemical Industry in the last Twenty-five Years" (Cantor Lectures. Succeeding lectures on February 20 and 27).

Tuesday, February 14

UNIVERSITY COLLEGE, LONDON, at 5.15.—Prof. S. R. K. Ghosh: "The Use of Museums. (2) The Archaeological Museum".*

Thursday, February 16

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, at 7.45.—Dr. C. Wilcocks: "Tuberculosis in Natives of Tropical and Sub-Tropical Regions."

Friday, February 17

INSTITUTION OF CHEMICAL ENGINEERS (at the Hotel Victoria, London), at 11.—Annual Corporate Meeting. Dr. William Oullen: "My Fifty Years of the Explosives Industry" (Presidential Address).

UNIVERSITY OF LONDON INSTITUTE OF EDUCATION (in association with the SOCIETY FOR THE PROTECTION OF SCIENCE AND LEARNING), at 5.30.—Prof. J. B. S. Haldane, F.R.S.: "Race in Fact and Theory".*

INSTITUTION OF MECHANICAL ENGINEERS, at 5.30.—Annual General Meeting.

W. H. Orr: "The Modern Paper-making Machine".

INSTITUTION OF CIVIL ENGINEERS (GLASGOW SECTION), at 7.30.—W. A. Tooke: "Dugald Clerk and the Gas Engine: His Life and Work" (Dugald Clerk Lecture).

ROYAL INSTITUTION, at 9.—Prof. G. T. R. Hill: "Aeroplane Controls".

Appointments Vacant

APPOINTMENTS are invited for the following appointments, on or before the dates mentioned:

DEMONSTRATOR in the Engineering Test Laboratory in the Royal Naval Engineering College, Devonport—The Director, Education Department, Admiralty, London, S.W.1 (February 11).

ASSISTANT (grade III) in the External Ballistic Department of the Ordnance Board, Woolwich—The Secretary, Ordnance Board, Royal Arsenal, Woolwich, S.E.18 (February 14).

JUNIOR LECTURER in CIVIL ENGINEERING in the University of the Witwatersrand—The Secretary, High Commissioner, South Africa House, Trafalgar Square, W.C.2 (February 22).

SENIOR TECHNICAL OFFICER in the Radio Department of the Royal Aircraft Establishment, South Farnborough, Hants—(February 25).

DIRECTOR OF SUGAR BEET RESEARCH—The Secretary, Sugar Commission, Queen Anne's Chambers, 41, Tothill Street, London, S.W.1 (February 28).

LECTURER in MATHEMATICS in the University of Aberdeen—The Secretary (March 7).

JUNIOR TECHNICAL ASSISTANT (electrical engineering) in the Royal Mint—The Secretary, Civil Service Commission, Burlington Gardens, London, W.1 (March 9).

READER in CHEMICAL ENGINEERING in the University of Bombay—The High Commissioner for India, Aldwych, London, W.C.2.

ASSISTANT MYCOLOGIST at the Imperial Mycological Institute, Ferry Lane, Kew, Surrey—The Director.

Science in Secondary Schools

SOCIAL organization is passing through a dynamic era. To-day the rate of change is higher, and, what is more important, we are more aware of it. For this reason the Spens report* is to be welcomed as a compendium of suggestions for meeting these changes, and above all as a clear statement that the duty of citizenship in a democracy renders it essential that all should be taught to understand and to think to the best of their ability. The report, the general trends of which were outlined in *NATURE* of January 21, p. 103, though of far-reaching importance, is perhaps not so revolutionary as was expected, which is all to the good ; for revolutionary changes, especially in such a highly organized system as that of education, would only result in confusion and counter-revolution. There is, after all, only a difference of degree between the pronouncements of Arnold and Sanderson, and those of such present-day educationists as Sir Richard Gregory, who once defined education as "the deliberate adjustment of a growing human organism to its environment". Furthermore, several of even the more important suggestions set forth in the Spens report are not new, but have already been made by other authoritative bodies. This illustrates the broad outlook and the democratic spirit adopted by the Spens Committee and the large body of witnesses which helped it in its deliberations.

Though the curriculum, it is considered, should have more regard to the vocational future of pupils rather than give so much time to training potential university students, a good general education is recommended. Thus does the report re-emphasize

the recommendations made earlier by the Hadow, Malcolm and Goodenough Committees. It is not suggested, however, that education has been virtually at a standstill since these recommendations were made. Much progress has indeed been made.

The teaching of science in secondary schools is subjected to much constructive criticism in the report. A plea is put forward for a more intimate alliance between subjects, provided the essential autonomy of each is preserved. It is clear, too, that certain scientific subjects are needlessly subdivided. Advantage should also be taken of the inherent curiosity of children about the practical concerns and activities of the world to bring their studies into closer contact with the practical affairs of life. This is best done by making the curriculum more general and freer, and most will agree with Dr. H. A. L. Fisher that is all to the good. The Spens Committee is thus led to urge strongly the claims of general science to a place in secondary school education.

The Committee considers that the teaching of science has lost touch with life itself, and for this reason has often failed either to give knowledge required or to stimulate the pupils' interest. This supports the pleas made by Sir William Bragg, in his presidential address to the Science Masters' Association in 1936, for the teaching of science in ways that will facilitate co-operation in dealing with national and international affairs—a strong plea in face of the present-day challenge to democracy.

There can be little doubt that in the early educative period more generalized science teaching is required. This was agreed so far back as 1934 at a conference arranged by the Science Masters'

* Report of the Consultative Committee on Secondary Education with Special Reference to Grammar Schools and Technical High Schools. Pp. xxviii+478. (London: H.M. Stationery Office, 1934.) 2s. 6d. net.

Association and the Institute of Education of the University of London. There the inclusion of biology in the syllabus was urged, which led Prof. E. N. da C. Andrade to admit that such a wider syllabus might lead to some superficiality of treatment, but he could see no particular harm in that—a statement of greater significance perhaps now than then. The interim report of the sub-committee appointed by the Science Masters' Association to consider the question of general science was much in favour of teaching the subject, and we commented (see *NATURE*, 138, 1030; 1936) on the efforts being made to change school science from its traditional, intensive and formal habit to a broader and more human shape. The addition of biology to a curriculum hitherto containing physics and chemistry only must of necessity broaden the cultural aims of science teaching. A general syllabus containing all three subjects aims, as no narrower syllabus can, at helping the pupil towards an intelligent understanding of his immediate environment, and thus forms a sounder basis for widening his interests and understanding in later life.

The Spens report emphasizes all this very thoroughly, and goes so far as to say that, in boys' schools especially, science teaching is too often restricted to the physical sciences, and in girls' schools too much botany is taught at the expense of biology. It is, therefore, of interest to compare the number of candidates in England and Wales offering these subjects in the School Certificate examinations in 1933 with those of 1937. In 1933, 27,007 candidates offered chemistry; in 1937, the number was 27,246—a negligible increase; physics has shown an increase from 18,860 to 20,826; botany a decrease from 13,094 to 8,487; biology an increase from 6,171 to 15,119; and general science an increase from 2,560 to 4,779. Although the period taken is comparatively short, it seems, therefore, that the recommendations made by various bodies in the past few years are bearing fruit. So this augurs well for the Spens report.

The report goes still further, however, in its recommendation that science should be more generalized. It suggests that astronomy and possibly some geology should be included; while in chemistry, a certain amount of attention should be given to organic studies. There seems no sound argument against such recommendations, which should have the whole-hearted support of every educationist and man of science. It is

interesting to note, too, that the final report of the sub-committee of the Science Masters' Association*, recently issued, puts forward similar views.

The Spens report gives special consideration to the peculiar problems of the country secondary schools, asserting that full advantage should be taken of their rural environment. The report recommends the teaching of more biology, agriculture, gardening and so forth, and the application of local surveys and farm statistics to geography and mathematics. The special position of a rural school is so obvious that to take advantage of the resources of the countryside seems a natural sequence. As optional subjects, the final report of the Science Masters' Association also recommends more biology, ecology, gardening and agriculture. While agreeing in principle with these conclusions, we suggest that they be treated with a certain amount of caution. The immediate environment of the rural school is naturally an advantage and convenience for the teacher. But more important than this is consideration for the future of the taught. Carried to ill-considered extremes, these recommendations would involve a 'rural population' receiving a rural education, and an 'urban population' a non-rural education. But there are children in the country more talented in the physical sciences, and the reverse applies to certain town children. Physics, chemistry and astronomy can and should be taught equally in both types of school; and in the town school, experimental biology can be taught, though of course not with such a wealth of material at hand as in the rural school. Few town children of to-day are absolutely unfamiliar with country life, or at any rate with plant and animal life, including man. While supporting the suggestion, therefore, that the school should take advantage of its environment, we would plead for a certain balance and plasticity in the individual school curriculum, in order to prevent the production of a certain number of 'square pegs in round holes'.

As we have stated over and over again, the narrowness of school science is due in no mean measure to the stranglehold of examinations. This applies especially to the School Certificate examination, which is the subject of criticism in the Spens and Science Masters' Association reports. At present, it tends to enforce an undesirable

* "The Teaching of General Science". Part 2. The Science Masters' Association. (London: John Murray, 1938). 2s. 6d.

uniformity in the curriculum, especially through its group system. The abolition of this grouping was recommended by the Secondary Schools Examination Council (Circular 1463, H.M. Stationery Office). This is now endorsed by the Spens Committee, and certain examining bodies have decided to adopt the recommendation. Such a recommendation will relieve the pupil from forced issues and encourage him more to follow his own bent. It is, for this reason, to be hoped that the recommendation will eventually be adopted by all examining bodies. Furthermore, both reports plead for a consideration of school records supplied by those who have taught the candidates. We welcome this suggestion, since it would relieve the examiners of what is tantamount to absolute authority in assessing educational merit, for which everyone, and especially the examiners themselves, would feel grateful.

It is gratifying to note that in the House of Commons on February 2, the Parliamentary Secretary to the Board of Education stated, in reply to a question, that the Spens report is being examined departmentally, and that "no time will be lost in getting into touch with local education authorities and other interested parties for the purpose of a full discussion of the important and constructive recommendations on such matters, among others, as technical high schools, the curriculum of grammar schools, the school certificate examination, and the inspection of private schools".

The recommendations enumerated above, even if only adopted in part, are bound to have their repercussions on the teacher as well as on the pupil. This is an important aspect of the problem which the Science Masters' Association report seems to have taken more to heart than has the Spens report. It is axiomatic that the right kind of teacher is required—one with a 'generous' training in science rather than the narrow specialist. Many teachers in secondary schools are university graduates who have specialized in one or two subjects. They would naturally feel embarrassed on being asked to teach subjects with which they are not familiar. In fact, according to the Science Masters' Association report, some of them are not in favour of general science for this reason. But that is merely shelving the problem. In any event, there is, as stated in this report, a tendency to exaggerate the difficulty, and the same report offers suggestions to such specialized teachers. There are, for example, Board of Education studentships to enable

teachers to improve their qualifications, university diplomas in certain subjects, evening courses in universities and colleges, vacation courses and so forth. There are also other facilities; for example, the Educational Advisory Board of the British Social Hygiene Council is offering a course for teachers in biology.

But these, at their best, can only help present-day teachers, and not even all those. It is the teacher of the future who will have to face the problem in its entirety. It is, therefore, the responsibility of the authorities to see that the most suitable teachers are available to deal with changes in educational curricula and methods. Most committees dealing with the problem look solely to the universities for aid and inspiration. But it is not the main function of a university to produce school teachers, although one cannot justifiably accuse them of being blind to the needs of the teaching profession. Much could be done before the future teacher makes his final choice of degree work. It is difficult, for example, to see the necessity for so many honours graduates in schools. A teacher with a general degree has, at any rate, sufficient actual knowledge of his subjects for school-teaching purposes, and more of them.

It is, we think, to the training colleges and education departments of the universities from which help might also be expected. Certain of them are already making efforts to produce the kind of teacher required to meet the changes in educational method. The education department of the University of Reading, for example, already offers a course on the teaching of rural science to graduates in science, agriculture and horticulture (see p. 305). This policy could, we think, with advantage be extended in such training institutions to the teaching of general science. Many student teachers enter their period of teacher-training either concurrently with their reading for a degree or after having graduated. They have already, therefore, a certain knowledge of scientific method and outlook, and should be easy material for elementary instruction in other scientific subjects and in general scientific methods. In this way, teachers with the requisite knowledge of general science could be supplied to the schools—teachers infinitely better equipped to teach general science than the first-class honours man who, in order to teach it competently, is forced to devote his spare time to extra courses of instruction after his period of training.

Science in the Modern World

The Social Function of Science

By J. D. Bernal. Pp. xvi+482. (London: George Routledge and Sons, Ltd., 1939.) 2s. 6d. net.

FOUR years ago a series of essays under the title "The Frustration of Science", to which Prof. J. D. Bernal himself contributed one on "Science and Industry", bore witness to the sense of social responsibility of individual scientific men at least, and to their concern at tendencies or forces which are preventing science from bringing its full benefits to mankind. Somewhat earlier, in "Scientific Research and Social Needs", Prof. Julian Huxley gave a popular picture of the extent to which scientific advance is influencing every aspect of everyday life and a brief forecast of some of the further possibilities if we can lessen or close the wide gap still existing between scientific knowledge and its application to the needs of humanity. In the interval, Lord Stamp in "The Science of Social Adjustment" has outlined something of a programme for research on some of the urgent problems arising from the impact of science on society. The events in the year or more since the publication of the present volume was first announced have made it, if anything, even more timely. Besides the more widespread interest in the reaction of science on society and the social consequences of scientific discoveries, scientific workers have become aware that, for the first time since the Renaissance, science itself is in danger, and that political forces are threatening not merely the direction but even the existence of science.

"The Social Function of Science" is fundamentally an elaboration of the books mentioned above. Addressed primarily to scientific workers in general, it ranges over the whole field of science, and indicates broadly its present position and structure, and the way in which the advance or the application of science is being delayed. It gives also some idea of the possibilities if the limitations or impediments to that advance or application can be removed, and like Lord Stamp, from whose book he quotes extensively, Prof. Bernal makes a number of specific proposals for investigation with the view of eliminating existing handicaps or obstacles.

The task Prof. Bernal has set himself is encyclopaedic; but he is to be congratulated alike on the width and balance of his survey. Important as detail may be, he has not allowed it to obscure his main theme, which is to give a comprehensive

picture of the whole situation. This he considers is the first condition of real progress. The present unsatisfactory position is largely due to lack of such a comprehensive view, and to the pursuit of short-range or sectional policies which may hinder the general advance. One of the main points in Prof. Bernal's argument is indeed the intricacy or complexity of the situation. Scientific advance in a particular field is determined not merely by the ability and number of the workers in that field, the way they are organized and the resources at their disposal, but also by their relations with the general body of men of science as well as by their whole social, industrial and political environment. He argues that attention to the social functions of science is required in the interests of scientific advance as well as in the interests of society.

Nor is this a new point of view. The social function of science is something which has grown up imperceptibly with science itself and in the same haphazard and unco-ordinated manner. This forms the theme of the second chapter of the book, which gives a concise but adequate historical approach. From this, the author proceeds to discuss the main structure of science at the present time. The existing organization of scientific research in Great Britain, both academic and industrial, the place of science in education and the training of the scientific worker, factors which limit the efficiency of research at the present time are reviewed, as well as the very topical questions of science and war and international relations of science.

Prof. Bernal makes many shrewd comments on present-day weaknesses and causes of inefficiency which individual scientific workers will be able to endorse from their own experience, if the author himself is limited rather to generalities. Moreover, while Prof. Bernal is a keen critic of many conditions for which scientific workers themselves have at most only an indirect responsibility, he leaves no room for doubt that there are many problems to which they could give their immediate attention, and that if science is to be of full use to society it must first set its own house in order.

The second part of the book gives Prof. Bernal's view of the possibilities which science offers if these limitations on its efficiency and utilization were removed. A series of chapters which are largely the counterpart of those in the

first part of the book, contain his own constructive suggestions in such matters as the training of the man of science, the reorganization of research, scientific communications, or publications, the finance of science and the strategy of scientific advance, and finally a picture of how science would be utilized in a beneficent transformation of human economy.

It is impossible in the space of a short review even to mention the main topics upon which Prof. Bernal touches. His chapters are calculated to stimulate thought and discussion, and if the plan of the book necessitates those interested in one particular topic, such as education or scientific publications, turning from one chapter to another widely separated in the second part of the book, instead of being able to follow it continuously, the arrangement undoubtedly serves the main purpose of the book. Whether in discussing such particular topics or in dealing with the general situation, Prof. Bernal rarely fails to touch on the fundamental problems. Even to scientific workers in their own particular field he often suggests new possibilities or points of view; but the treatment is never allowed to degenerate into disconnected discussions which are unrelated to the main problem of the future of science and its ability to serve society.

Prof. Bernal regards the present social disorders as primarily due to science progressing beyond the social forms in which during the last five hundred years it has developed. The future of science depends on the creation of a new social form and demands the intelligent management of science by society as a whole. Accordingly he argues that scientific workers cannot be indifferent to politics and must avoid becoming pawns of the major social forces, although he does not believe that as men of science they should join any particular party.

Some minor criticisms may be offered. The book bears some evidence of hasty writing. Some quotations are repeated *in extenso* where a reference might easily have served. The appendix on expenditure on industrial research might well have been omitted. A table which omits the names of firms pre-eminent in industrial research at the present time and representing a total expenditure of less than £120,000 per annum on research in Great Britain is too misleading to give even a rough idea of the situation. Again, the account of Soviet science and the development of a scientific outlook in the U.S.S.R. would have gained in value by some indication as to whether or not the greater use of science under that regime is accompanied by any greater freedom of direction and content of scientific investigation than under Fascism. The section on associations of scientific workers is rather unbalanced and is strangely free from Prof. Bernal's usual pertinent and constructive criticism. He omits all reference to A. M. Carr-Saunders and P. A. Wilson's fine study of this problem, and one is inclined to suspect that Prof. Bernal himself is among the many scientific workers who have overlooked the significance of that study.

These and other points, however, are minor matters. Some may well be rectified in a later edition, and meanwhile, at a time when the personal security which has formerly been one of the chief triumphs of civilization has diminished almost to vanishing point, scientific workers may well be grateful for this well-balanced analysis of the intricate relations between science and contemporary life and its constructive proposals to remedy the mistakes and failures of the past. At least, it is to be hoped this book will not, like so many other constructive and suggestive works in recent years, be ignored by their professional associations.

R. BRIGHTMAN.

Nutritional Science

Science and Nutrition

By A. L. Bacharach, with a Preface by Prof. J. C. Drummond. (Changing World Library, No. 11.) Pp. xiv+154. (London: C. A. Watts and Co., Ltd., 1938.) 2s. 6d. net.

THIS is a book with a flavour all its own. The author himself modestly defines his aim as being to "put before the reader the kind of methods used in the laboratory study of nutritional problems and the kind of knowledge obtained thereby". That he has succeeded admirably in this there can

be no doubt. But he has done a good deal more as well. The book resembles neither the ordinary 'elementary science primer' on one hand nor the usual type of 'popular science for the layman' on the other. It puts one in mind rather of a series of essays, discursive, stimulating, witty, such as one might expect to find in one of the weekly literary or political reviews. With no sacrifice of accuracy, the text is enlivened by the catholic tastes as well as by the stylistic gifts of the author. It is for this reason that Mr. Bacharach's little book will be read with so much entertainment and

profit not only by the man in the street to whom, as he tells us, it is principally addressed, but also by the specialist.

In the introduction a justification is given for the predominantly chemical treatment which the subject is accorded :

"Walter Pater said that all art aspires towards the nature of music ; is it not also true to say that all biology aspires towards interpretation in terms of atomic physics ? It will probably be conceded that chemical interpretations are a little nearer to the physical asymptote than are physiological. If so, the urgent need to guide the layman away from the mists of obscurantism—naturalism, vitalism, and what not—in his application of scientific knowledge to ordinary human and social problems, must surely justify the presentation to him of biological facts in terms as far removed as possible from the dangers of mystification. I honestly believe that there is a better chance of doing this on the chemical than on the physiological plane."

It might be argued that this reasoning is somewhat stiff going for the 'man in the street' aforementioned, as are also for example such technical points as the chemical equation for the esterification of mixed glycerides (p. 31), or the statement (p. 142) that "the requirements of the population as a whole will presumably be distributed about M/N , in accordance with the normal frequency distribution curve, though nothing at all is known about the breadth or steepness of the curve that indicates the normal variations in need for this or for any other dietary essential". But this objection cannot be sustained, because it is explained (p. ix) that it is for the "interested and educated layman" that the book has been written ; and its author has also assumed (p. 11) that—

"the reader may well be already acquainted with the general features of human nutrition—the broad chemistry of carbohydrates, fats, and protein, the kinds of food in which they occur and their relative amounts, the processes of breaking down—catabolism—to simpler constituents and building up again—anabolism—to the more complex substances of the living body, the two processes together constituting the *metabolism* of the organism."

Incidentally, another justification offered for the essentially chemical approach is that the lay reader is more likely to be acquainted with chemistry than with biology. "The chances, alas, that he will ever have been instructed even in the earliest rudiments of animal physiology are still to-day so small as to be negligible." Fortunately, biology is to-day being given increasing recognition in the average school syllabus, and it may be that

in a few years time this reproach will no longer be valid.

As Mr. Bacharach is largely concerned with describing the results of investigations in the laboratory, "particularly with experiments on small animals", it was a happy touch to dedicate his book (in impeccable Latin phrases) to the albino rat. An introductory chapter is devoted to a justification, and a very persuasive one, of the use of laboratory animals—not as a substitute for clinical studies, but as "biological reagents".

Following on this introduction, the second section of the book deals with "Classical Nutritional Science", that is, with carbohydrates, fats and proteins. Next is a treatment of the mineral elements, "major" as well as "trace", and of hormones. After this we are given an account of the vitamins. In this portion the author makes no pretence to deal even in outline with the whole field, but wisely contents himself with a series of illustrative examples—vitamin A serves to show how vitamins are detected, vitamin C how they are measured, and D how they have been identified.

The final portion of the book deals with diet and human health, first with "the necessity for the optimal", and then—coming down to earth—with the "absence of the optimal". This last aspect of the problem could not be better summed up than as it is by Prof. J. O. Drummond in his most attractively written preface :

"The survival of democracy or its annihilation during the next few years may easily be determined by the measure of attention given in the various countries to what have come to be called the problems of human nutrition. . . . The great majority of the 'problems of nutrition', about which one hears so much nowadays, have been solved by the scientist, and they are now translated into problems of economics or political science. . . . The incidence of pellagra in the 'corn-belt' of the United States still sharply reflects the rise and fall of poverty and unemployment. It is not a question of nicotinic acid ; it is simply one of £. s. d. The only real problem of nutrition in England to-day is the task of making available to the poorest person the 'protective foods', such as milk, butter, fresh salads, and fruit, which are essential for health."

Referring to so-called 'minimal' diets, Mr. Bacharach adds a much-needed corollary. "When a constructional firm is asked to tender for a railway bridge, it is asked to tender for a railway bridge that will do its job as well as possible, and not for one that will be just 'safe' or 'minimal' within the financial ability of the customer to pay. It seems unfortunate that, in matters of human construction, a different principle should be adopted."

LESLIE J. HARRIS.

The Air Almanac

The Air Almanac, 1939, January-March (Air Publication 1602.) Prepared by H.M. Nautical Almanac Office on behalf of the Air Ministry. Pp. 188+xii. (H.M. Stationery Office, 1938.) 5s. net.

THE British "Air Almanac", an almanac specially adapted to the requirements of air navigation, was published for the first time for the last quarter of the year 1937. A review of this publication appeared in these pages. Experience with the almanac in its original form showed the desirability of certain changes. These changes were required, in the first place, in order to shorten the time occupied in working out the results, and, in the second place, to reduce the amount of turning over of pages, because the air navigator often has very cold fingers. Another consideration was the numbing effect on the brain of a long flight; in order to reduce the possibility of error, it was desirable to make the working out of the results so far as possible a matter of pure routine. To meet these requirements, the "Air Almanac" has been completely remodelled. As compared with the original almanac, in the remodelled edition the amount of interpolation has been reduced to a minimum: the number of separate tables that have to be referred to has been reduced, so avoiding turning over pages; and the way of extracting the required information has been standardized.

It may be recalled that the quantities tabulated in the "Air Almanac" are the Greenwich hour angle expressed in arc (that is, the hour angle measured from the meridian of Greenwich) and the declination. These are the two quantities that are required for drawing a position line. For the stars the simplification is introduced of tabulating the Greenwich hour angle of the First Point of Aries. To obtain the Greenwich hour angle of a star, the sidereal hour angle of the star (the hour angle measured westwards from the First Point of Aries) must be added to the Greenwich hour angle of the First Point of Aries. The sidereal hour angle of a star is a quantity that varies slowly through the year and, to the degree of accuracy of tabulation employed in the "Air Almanac", can be taken as constant for the period of three months covered by each issue of the Almanac in its new form.

In the new issue of the Almanac, the intervals of tabulation have been reduced for the sun, moon and planets. The data for the sun and moon, formerly given at hourly intervals, are now given at intervals of ten minutes; the data for the planets, formerly given at intervals of six hours,

are now given at hourly intervals. The interpolations required for the extraction of the data for a given instant of time are accordingly much reduced and simplified. The original publication consisted of a permanent portion containing interpolation and other tables, together with explanation and description, and ephemeral loose-leaf sheets, each one of which contained the data for two days, the stars on one side and the sun, moon and planets on the other. These two portions have now been combined, so that each quarterly issue in the new form is self-contained.

The reduction in the intervals of tabulation has necessitated doubling the number of pages, so that each sheet now caters for one day only. The sheets are perforated and can be torn off in succession as they cease to be required. The increase in size of the Almanac has made possible the tabulation of sunrise, sunset, twilight, moonrise and moonset for each day. The parallax in altitude of the moon is tabulated for each day in the form of a critical table and the phase of the moon is also given. The planetary data are restricted to the three planets that are most favourably placed for observation. The arrangement of the data has been considered very carefully and the maximum possible information has been given in the space available, but without any appearance of undue crowding.

The introduction and explanation of the use of the tables is given after the daily sheets. The list of stars (fifty in all), together with magnitudes, sidereal hour angles and declinations, and an interpolation table for the interpolation of the Greenwich hour angles of the First Point of Aries and of the sun, are given inside the front cover. Space is provided also for a table of dome refractions, for use when observations are made through a dome. A flap is provided which gives the interpolation tables for the Greenwich hour angle of the moon and of the planets and for moonrise and moonset, as well as the Pole Star table and a table for the conversion of arc into time.

Of the various Air Almanacs that have been published, this Almanac in its remodelled form is undoubtedly the most convenient and compact. The Nautical Almanac Office, which has undertaken the computation of the Almanac for the Air Ministry, by agreement with the Admiralty, is to be congratulated on an excellent production, and the Stationery Office deserves to be complimented on a clearly printed and well-bound volume.

It may be added that the tabulated data, given to the nearest minute of arc, are sufficiently accurate for most requirements of surface navigation.

Man in a Chemical World :

the Service of Chemical Industry. By A. Cressy Morrison. Pp. xii+292. (London: Scientific Book Club, n.d.) 2s. 6d.

THIS volume is an interesting example of the publications of the Scientific Book Club, which are available to members at the uniform price of half-a-crown. Described as "a straight-from-the-shoulder account of the activities of chemical industry in converting the discoveries of science into day-to-day necessities of Everyman", it was originally produced under the auspices of the Executive Committee of the American Chemical Industries Tercentenary, in connexion with the celebration in 1935 of the three-hundredth anniversary of the birth of chemical industry in the United States. Its object, as explained in a foreword, "is to impress the man in the street with the fact that the chemical industries of the United States render a service that touches practically every activity in which he engages". This object is amply attained in a simple and able account of the multifarious achievements of chemistry in industry and everyday life, set out under such headings as "Nature Points the Way", "Chemistry in Overalls", "Keeping Well", "Feeding Millions", "From Papyrus to Television", etc.

A remarkable amount of interesting information has been packed, in an attractive form, into this low-priced volume. The language is plain, and there are no chemical formulae to puzzle the lay reader. The text is well printed in a bold type by the Scribner Press in the United States. There are a few ingenious pictorial diagrams; but some of the illustrations are neither instructive nor decorative. J. R.

Die tierischen Parasiten des Menschen

Von Prof. Walter Stenpell. Pp. viii+226. (Jena: Gustav Fischer, 1938.) 12 gold marks.

IN a more convenient and compact form than has hitherto appeared in Germany, this work essays the description of the parasitic fauna of man. Morphological characters are summarized clearly and briefly, but with sufficient detail for identification of all the common parasites. But the rarer forms are also represented (more briefly and in small type) as may be judged by the inclusion of the python parasite *Armillifer moniliformis*, with five cases recorded from man, and of several insects the connexion of which with human disease is slight; in all, 192 parasites are described. A special feature is the illustration of the text by original schematic figures, which are often accompanied by corresponding photographs.

Since the book is intended to be of service to general zoologists rather than to specialists, morphology takes precedence over physiological, biological, medical and epidemiological aspects, and these are seriously touched upon only in the case of prominent forms, like *Plasmodium*, *Trypanosoma*, the tapeworms and a few arthropods. The publishers are to be congratulated on the clearness of the printing and reproduction of illustrations. *Wuchereria* (pp. 134, 135 and index) should be *Wuchereria*.

Insects of Citrus and other Subtropical Fruits

By Prof. Henry J. Quayle. Pp. x+588. (Ithaca, N.Y.: Comstock Publishing Co., 1938.) 5 dollars.

THE field covered by this work is an extensive one which has not been previously dealt with in a comprehensive book form. Its author has had wide experience of citrus fruit cultivation, and its insect enemies, not only in California but also in other lands. While the book deals with all the main citrus-affecting insects, other subtropical fruit insects are also included, notably those affecting avocado, Persian walnut, vinifera grape, fig, almond, olive, date and some others. The life-histories of the chief pests are described and usually figured. Their natural enemies, where noteworthy, are discussed, and artificial methods of control are fully entered into. The subject matter of this book is up-to-date while the illustrations are often new and original. It is a work that is to be recommended to all concerned with citrus cultivation and more particularly to growers in the United States.

Japanese Minerals in Pictures

By T. Ito. In 4 vols. Vol. 1. Pp. xiv+152+27 plates. (Tokyo: The Author, Tokyo Imperial University, 1937.) 12 yen.

A VERY handsomely illustrated mineralogy with the text in Japanese is Prof. Takeo Ito's "Japanese Minerals in Pictures", of which the first of the four volumes was published in Tokyo in 1937. In 152 pages with 96 crystal drawings the elements, sulphides, and fluorides are described. A fourteen-page key in English gives a brief account of the 38 minerals depicted in the 27 plates, with brief notes on the chief occurrences of the minerals in Japan. Twenty of the plates are reproduced in colour and some of these are among the best coloured representations of minerals printed hitherto. The specimens illustrated are picked specimens and will be the envy of mineral collectors. These plates are the special features of the book and will earn it a place on the shelves of mineralogical libraries all over the world.

Useful Trees and Shrubs :

Being a Card File of Data on approximately 500 Hardy Woody Plants in Common Use as Ornamentals. Compiled and prepared by Prof. Florence Bell Robinson. 494 Cards. 6 in. x 4 in. (Champaign, Ill.: The Garrard Press, 1938.) 4.50 dollars.

THIS card index will be useful to those interested in hardy shrubs and trees, though it is difficult to see that it has any advantage over the available books as a reference work. Certain blank spaces on the cards are said to be an invitation to the user to add his own observations and sketches; if used in this way there is no doubt that much benefit would accrue to the user, and in this case the card index scheme admits of profitable expansion of the record. Notes on the cards refer to habitat; form; colour; bark; season of foliage; flower and fruit; 'cleanliness' (that is, susceptibility to pest and disease); pruning; aspect and value.

Fluorescence and Phosphorescence

By Dr. E. Hirschlaff. (Methuen's Monographs on Physical Subjects.) Pp. vi+130. (London: Methuen and Co., Ltd., 1938.) 3s. 6d. net.

THIS new addition to Methuen's series of monographs on physical subjects makes a valiant attempt to cope with the whole of the subject of luminescence, a task particularly difficult at the present time in view of the rapid advances taking place. The book may, on the whole, be recommended to the general reader. Those already familiar with the subject are likely to discover a number of inadequacies. One feels that the directions of most rapid progress at the present time have not been sufficiently emphasized, and it might have been a good deal wiser to confine the book to one of the more important aspects of the subject. In the result there are twelve chapters, of which the first and last are the worst. Chapter i, subtitled "The Experiments", is almost meaningless in its narrow limits of three pages. Such "experiments" as are here mentioned could easily have been brought naturally into line in the later sections of the book. Chapter xii is concerned with technical applications. The most important application of luminescent solids is in discharge devices, and Dr. Hirschlaff's treatment of this aspect cannot be considered as more than sketchy.

The emphasis of the book may be gathered from the fact that seven of the chapters are given up to the problems of fluorescence in gases, liquids and solutions. Two chapters deal specifically with luminescence in solids, and there is also an account of 'cathodo-luminescence'. It is a pity that the references to original papers given at the foot of each chapter are almost entirely confined to Continental workers.

J. T. R.

Hydroids of the Pacific Coast of Canada and the United States

By C. McLean Fraser. Pp. 208+44 plates. (Toronto: University of Toronto Press, 1937). 2.50 dollars.

TO open this book is to be at once reminded of Hincks' "Hydroid Zoophytes", now seventy years old, or of Dr. George Johnston's book of a generation before, both of them beloved by innumerable naturalists. Here, in like manner, Prof. McLean Fraser has produced, in handy form and copiously illustrated, an account of the rich hydroid fauna of the Pacific Coast, from California all the way to Bering Sea. We are struck, at first sight, by the curious likeness of this fauna to the British fauna; many species are identical, such as Linnaeus's *Obelia geniculata* and *Sertularella polyzonias*, or Ellis and Solander's *Halecium muricatum*. Others, not so familiar as these, such as the various species of *Selaginopsis*, carry an Arctic fauna round the world from the Murman Coast and the Siberian Sea. But there are not wanting many others, strange to our European seas. The book is an interesting one to the naturalist at home, and will become an indispensable one to the many naturalists out west by the Pacific.

D. W. T.

A Hand through Time:

Memories—Romantic and Geological; Studies in the Arts and Religion; and the Grounds of Confidence in Immortality. By Dr. Edward Greenly. Vol. 1. Pp. xvi+378+60 plates. Vol. 2. Pp. viii+379+774+15 plates. (London: Thomas Murby and Co., 1938.) 18s. net.

DR. EDWARD GREENLY is best known as the author of a comprehensive memoir on the geology of Anglesey and of a geological map of that island, both published by the Geological Survey. Practically the whole of his long life has been devoted to geological research and, during his wife's lifetime, he owed much to her helpful co-operation. A large part of his book is devoted to a character study of Mrs. Greenly, with which is interwoven the author's autobiography. This account of a long life's companionship will interest especially Greenly's wide circle of friends and acquaintances.

The book is somewhat discursive, but it includes a chronicle of its author's scientific activities, and there are many interesting geological reminiscences. Dr. Greenly's career as a geologist commenced in Scotland in 1889, where he was attached to the Geological Survey for a few years. There he came into contact with Peach, Horne, Clough and other geologists of the period, and he gives an interesting account of survey work in Scotland at that time. On leaving the Survey he proceeded to Anglesey, where he spent twenty years unravelling the complex geology of that island. The account of this masterly piece of research should prove of interest to all geologists, whether or not they are acquainted with its author.

Physical Geography for Indian Students:

being a completely revised and enlarged edition of Simmons and Stenhouse's "Class-Book of Physical Geography". By Dr. Cyril S. Fox. Pp. xii+564+5 plates. (London: Macmillan and Co., Ltd., 1938.) 7s. 6d.

ALTHOUGH primarily intended for Indian students, this revised edition of a well-known text-book makes a wider appeal. The coloured maps which illustrate various aspects of map reading have been chosen from the Survey of India, and many of the examples of physical processes have been chosen from India, but the book as a whole covers all the groundwork of physical geography, including the distribution of climate, plants and animals, and should be useful in all English-speaking lands as an introduction to geography. One of the greatest difficulties confronting the writers of an elementary book on these subjects is the avoidance of over-simplification in the discussion on problems of climate. It is easy to generalize and difficult to avoid complexity. On the whole these pitfalls have been well avoided, but a little revision would not be amiss on the subjects of cyclones, world distribution of atmospheric pressure and ocean currents. On the whole, however, the book is admirable and the many exercises are a valuable feature.

R. N. R. B.

Natural Philosophy and Human Cultures*

By Prof. Niels Bohr, For. Mem. R.S.

IT is only with great hesitation that I have accepted a kind invitation to address this assembly of distinguished representatives of the anthropological and ethnographical sciences of which I, as a physicist, have of course no first-hand knowledge. Still, on this special occasion, when even the historical surroundings speak to everyone of us about aspects of life other than those discussed at the regular congress proceedings, it might perhaps be of interest to try with a few words to direct attention to the epistemological aspect of the latest development of natural philosophy and its bearing on general human problems. Notwithstanding the great separation between our different branches of knowledge, the new lesson which has been impressed upon physicists regarding the caution with which all usual conventions must be applied as soon as we are not concerned with everyday experience, may, indeed, be suited to remind us in a novel way of the dangers, well known to humanists, of judging from our own point of view cultures developed within other societies.

Of course it is impossible to distinguish sharply between natural philosophy and human culture. The physical sciences are, in fact, an integral part of our civilization, not only because our ever increasing mastery of the forces of Nature has so completely changed the material conditions of life, but also because the study of these sciences has contributed so much to clarify the background of our own existence. What has it not meant in this respect, that we no more consider ourselves as privileged in living at the centre of the universe, surrounded by less fortunate societies inhabiting the edges of the abyss, but that through the development of astronomy and geography we have realized that we are all sharing a small spherical planet of the solar system, which again is only a small part of still larger systems. How forceful an admonition about the relativity of all human judgements have we not also in our days received through the renewed revision of the presuppositions underlying the unambiguous use of even our most elementary concepts such as space and time, which, in disclosing the essential dependence of every physical phenomenon on the point of view of the observer, has contributed so largely to the unity and beauty of our whole world-picture.

While the importance of these great achievements

for our general outlook is commonly realized, it is scarcely yet so as regards the unsuspected epistemological lesson which the opening of quite new realms of physical research has given us in the most recent years. Our penetration into the world of atoms, hitherto closed to the eyes of man, is indeed an adventure which may be compared with the great journeys of discovery of the circumnavigators and the bold explorations of astronomers into the depths of celestial space. As is well known, the marvellous development of the art of physical experimentation has not only removed the last traces of the old belief that the coarseness of our senses would for ever prevent us from obtaining direct information about individual atoms, but has even shown us that the atoms themselves consist of still smaller corpuscles which can be isolated and the properties of which can be investigated separately. At the same time we have, however, in this fascinating field of experience been taught that the laws of Nature hitherto known, which constitute the grand edifice of classical physics, are only valid when dealing with bodies consisting of practically infinite numbers of atoms. The new knowledge concerning the behaviour of single atoms and atomic corpuscles has, in fact, revealed an unexpected limit for the subdivision of all physical actions extending far beyond the old doctrine of the limited divisibility of matter, and giving every atomic process a peculiar individual character. This discovery has, in fact, yielded a quite new basis for the understanding of the intrinsic stability of atomic structures, which, in the last resort, conditions the regularities of all ordinary experience.

How radical a change in our attitude towards the description of Nature this development of atomic physics has brought about is perhaps most clearly illustrated by the fact that even the principle of causality, so far considered as the unquestioned foundation for all interpretation of natural phenomena, has proved too narrow a frame to embrace the peculiar regularities governing individual atomic processes. Certainly everyone will understand that physicists have needed very cogent reasons to renounce the ideal of causality itself; but in the study of atomic phenomena we have repeatedly been taught that questions which were believed to have received long ago their final answers had most unexpected surprises in store for us. You will surely all have heard about the riddles regarding the most elementary

* Address given at Kronborg Castle during the excursion to Elanore of the International Congress of Anthropological and Ethnological Sciences, Copenhagen, August, 1938.

properties of light and matter which have puzzled physicists so much in recent years. The apparent contradictions which we have met in this respect are, in fact, as acute as those which gave rise to the development of the theory of relativity in the beginning of this century, and have, just as the latter, only found their explanation by a closer examination of the limitation imposed by the new experiences themselves on the unambiguous use of the concepts entering into the description of the phenomena. While in relativity theory the decisive point was the recognition of the essentially different ways in which observers moving relatively to each other will describe the behaviour of given objects, the elucidation of the paradoxes of atomic physics has disclosed the fact that the unavoidable interaction between the objects and the measuring instruments sets an absolute limit to the possibility of speaking of a behaviour of atomic objects which is independent of the means of observation.

We are here faced with an epistemological problem quite new in natural philosophy, where all description of experiences has so far been based upon the assumption, already inherent in ordinary conventions of language, that it is possible to distinguish sharply between the behaviour of objects and the means of observation. This assumption is not only fully justified by all everyday experience, but even constitutes the whole basis of classical physics, which, just through the theory of relativity, has received such a wonderful completion. As soon as we begin to deal, however, with phenomena like individual atomic processes which, due to their very nature, are essentially determined by the interaction between the objects in question and the measuring instruments necessary for the definition of the experimental arrangements, we are forced to examine more closely the question of what kind of knowledge can be obtained concerning these objects. In this respect we must, on one hand, realize that the aim of every physical experiment—to gain knowledge under reproducible and communicable conditions—leaves us no choice but to use everyday concepts, eventually refined by the terminology of classical physics, not only in all accounts of the construction and manipulation of the measuring instruments but also in the description of the actual experimental results. On the other hand, it is equally important to understand that just this circumstance implies that no result of an experiment concerning a phenomenon which, in principle, lies outside the range of classical physics, can be interpreted as giving information about independent properties of the object; but is inherently connected with a definite situation in the description of which the measuring instruments

interacting with the objects also enter essentially. This last fact gives the straightforward explanation of the apparent contradictions which appear when results about atomic objects obtained by different experimental arrangements are tentatively combined into a self-contained picture of the object.

Information regarding the behaviour of an atomic object obtained under definite experimental conditions, may, however, according to a terminology often used in atomic physics, be adequately characterized as *complementary* to any information about the same object obtained by some other experimental arrangement excluding the fulfilment of the first conditions. Although such kinds of information cannot be combined into a single picture by means of ordinary concepts, they represent indeed equally essential aspects of any knowledge of the object in question which can be obtained in this domain. It is the recognition of such a complementary character of the mechanical analogies by which one has tried to visualize the individual radiative effects which has, in fact, led to an entirely satisfactory solution of the riddles of the properties of light alluded to above. In the same way, it is only by taking into consideration the complementary relationship between the different experiences concerning the behaviour of atomic corpuscles, that it has been possible to obtain a clue to the understanding of the striking contrast between the properties of ordinary mechanical models and the peculiar laws of stability governing atomic structures which form the basis for every closer explanation of the specific physical and chemical properties of matter.

Of course I have no intention, on this occasion, of entering more closely into such details, but I hope that I have been able to give a sufficiently clear impression of the fact that we are here in no way concerned with an arbitrary renunciation as regards the detailed analysis of the almost overwhelming richness of our rapidly increasing experience in the realm of atoms. On the contrary, we have to do with a rational development of our means of classifying and comprehending new experience which, due to its very character, finds no place within the frame of causal description suited only to account for the behaviour of objects so long as this behaviour is independent of the means of observation. Far from containing any mysticism contrary to the spirit of science, the viewpoint of 'complementarity' forms indeed a consistent generalization of the ideal of causality.

However unexpected this development may appear in the domain of physics, I am sure that many of you will have recognized the close analogy between the situation as regards the analysis of atomic phenomena, which I have described, and characteristic features of the problem of observation

in human psychology. Indeed, we may say that the trend of modern psychology can be characterized as a reaction against the attempt at analysing psychical experience into elements which can be associated in the same way as are the results of measurements in classical physics. In introspection, it is clearly impossible to distinguish sharply between the phenomena themselves and their conscious perception, and although we may often speak of lending our attention to some particular aspect of a psychical experience, it will appear on closer examination that we really have to do, in such cases, with mutually exclusive situations. We all know the old saying that, if we try to analyse our own emotions, we scarcely possess them any longer, and in that sense we recognize between psychical experiences, for the description of which words such as 'thoughts' and 'feelings' are adequately used, a complementary relationship similar to that between the experiences regarding the behaviour of atoms obtained under different experimental arrangements and described by means of different analogies taken from our usual ideas. By such a comparison it is, of course, in no way intended to suggest any closer relation between atomic physics and psychology, but merely to stress an epistemological argument common to both fields, and thus to encourage us to see how far the solution of the relatively simple physical problems may be helpful in clarifying the more intricate psychological questions with which human life confronts us, and which anthropologists and ethnologists so often meet in their investigations.

Coming now closer to our subject of the bearing of such viewpoints on the comparison of different human cultures, we shall first stress the typical complementary relationship between the modes of behaviour of living beings characterized by the words 'instinct' and 'reason'. It is true that these words are used in very different senses; thus instinct may mean motive power or inherited behaviour, and reason may denote deeper sense as well as conscious argumentation. What we are concerned with is, however, only the practical way in which these words are used to discriminate between the different situations in which animals and men find themselves. Of course, nobody will deny our belonging to the animal world, and it would even be very difficult to find an exhaustive definition characterizing man among the other animals. Indeed, the latent possibilities in any living organism are not easily estimated, and I think that there is none of us who has not sometimes been deeply impressed by the extent to which circus animals can be drilled. Not even with respect to the conveyance of information from one individual to another would it be possible

to draw a sharp separation between animals and man; but of course our power of speech places us in this respect in an essentially different situation, not only as regards the exchange of practical experience, but also and above all as regards the possibility of transmitting through education to children the traditions concerning behaviour and reasoning which form the basis of any human culture.

As regards reason compared with instinct, it is, above all, essential to realize that no proper human thinking is imaginable without the use of concepts framed in some language which every generation has to learn anew. This use of concepts is, in fact, not only to a large extent suppressing instinctive life, but stands even largely in an exclusive relationship of complementarity to the display of inherited instincts. The astonishing superiority of lower animals compared with man in utilizing the possibilities of Nature for the maintenance and propagation of life has certainly often its true explanation in the fact that, for such animals, we cannot speak of any conscious thinking in our sense of the word. At the same time, the amazing capacity of so-called primitive people to orientate themselves in forests or deserts, which, though apparently lost in more civilized societies, may on occasion be revived in any of us, might justify the conclusion that such feats are only possible when no recourse is taken to conceptual thinking, which on its side is adapted to far more varied purposes of primary importance for the development of civilization. Just because it is not yet awake to the use of concepts, a new-born child can scarcely be reckoned as a human being; but belonging to the species of man, it has, of course, though more helpless a creature than most young animals, the organic possibilities of receiving through education a culture which enables it to take its place in some human society.

Such considerations confront us at once with the question whether the widespread belief that every child is born with a predisposition for the adoption of a specific human culture is really well-founded, or whether one has not rather to assume that any culture can be implanted and thrive on quite different physical backgrounds. Here we are of course touching a subject of still unsettled controversies between geneticists, who pursue most interesting studies on the inheritance of physical characters. In connexion with such discussions, however, we must above all bear in mind that the distinction between the concepts genotype and phenotype, so fruitful for the clarification of heredity in plants and animals, essentially presupposes the subordinate influence of the external conditions of life on the characteristic properties of the species. In the case of the specific cultural

characters of human societies the problem is, however, reversed in the sense that the basis for the classification is here the traditional habits shaped by the histories of the societies and their natural environments. These habits, as well as their inherent presuppositions, must therefore be analysed in detail before any possible influence of inherited biological differences on the development and maintenance of the cultures concerned can be estimated. Indeed, in characterizing different nations and even different families within a nation, we may to a large extent consider anthropological traits and spiritual traditions as independent of each other, and it would even be tempting to reserve by definition the adjective 'human' for just those characters which are not directly bound to bodily inheritance.

At first sight, it might perhaps appear that such an attitude would mean unduly stressing merely dialectic points. But the lesson which we have received from the whole growth of the physical sciences is that the germ of fruitful development often lies just in the proper choice of definitions. When we think, for example, of the clarification brought about in various branches of science by the argumentation of relativity theory, we see indeed what advance may lie in such formal refinements. As I have already hinted earlier in this address, relativistic viewpoints are certainly also helpful in promoting a more objective attitude as to relationships between human cultures, the traditional differences of which in many ways resemble the different equivalent modes in which physical experience can be described. Still, this analogy between physical and humanistic problems is of limited scope and its exaggeration has even led to misunderstandings of the essence of the theory of relativity itself. The unity of the relativistic world picture, in fact, implies the possibility for any one observer to predict within his own conceptual frame how any other observer will co-ordinate experience within the frame natural to him. The main obstacle to an unprejudiced attitude towards the relation between various human cultures is, however, the deep-rooted differences of the traditional backgrounds on which the cultural harmony in different human societies is based and which exclude any simple comparison between such cultures.

It is above all in this connexion that the viewpoint of complementarity offers itself as a means of coping with the situation. In fact, when studying human cultures different from our own, we have to deal with a particular problem of observation which on closer consideration shows many features in common with atomic or psychological problems, where the interaction between objects and measuring tools, or the

inseparability of objective content and observing subject, prevents an immediate application of the conventions suited to accounting for experiences of daily life. Especially in the study of cultures of primitive peoples, ethnologists are, indeed, not only aware of the risk of corrupting such cultures by the necessary contact, but are even confronted with the problem of the reaction of such studies on their own human attitude. What I here allude to is the experience, well known to explorers, of the shaking of their hitherto unrealized prejudices through the experience of the unsuspected inner harmony human life can present even under conventions and traditions most radically different from their own. As a specially drastic example I may perhaps here recall the extent to which in certain societies the roles of men and women are reversed, not only regarding domestic and social duties but also regarding behaviour and mentality. Even if many of us, in such a situation, might perhaps at first shrink from admitting the possibility that it is entirely a caprice of fate that the people concerned have their specific culture and not ours, and we not theirs instead of our own, it is clear that even the slightest suspicion in this respect implies a betrayal of the national complacency inherent in any human culture resting in itself.

Using the word much as it is used, in atomic physics, to characterize the relationship between experiences obtained by different experimental arrangements and capable of visualization only by mutually exclusive ideas, we may truly say that different human cultures are complementary to each other. Indeed, each such culture represents a harmonious balance of traditional conventions by means of which latent potentialities of human life can unfold themselves in a way which reveals to us new aspects of its unlimited richness and variety. Of course, there cannot, in this domain, be any question of such absolutely exclusive relationships as those between complementary experiences about the behaviour of well-defined atomic objects, since scarcely any culture exists which could be said to be fully self-contained. On the contrary, it is well known from numerous examples how a more or less intimate contact between different human societies can lead to a gradual fusion of traditions, giving birth to a quite new culture. The importance in this respect of the mixing of populations through emigration or conquest for the advancement of human civilization need scarcely be recalled. It is, indeed, perhaps the greatest prospect of humanistic studies, to contribute through an increasing knowledge of the history of cultural development to that gradual removal of prejudices which is the common aim of all science.

As I stressed in the beginning of this address, it is, of course, far beyond my capacities to contribute in any direct way to the solution of the problems discussed among the experts at this congress. My only purpose has been to give an impression of a general epistemological attitude which we have been forced to adopt in a field as far from human passions as the analysis of simple physical experiments. I do not know, however, whether I have found the right words to convey this impression, and before I conclude, I may perhaps be allowed to relate an experience which once most vividly reminded me of my deficiencies in this respect. In order to explain to an audience that I did not use the word 'prejudice' to imply any condemnation of other cultures, but merely to characterize our necessarily prejudiced con-

ceptual frame, I referred jokingly to the traditional prejudices which the Danes cherish with regard to their Swedish brothers on the other side of the beautiful Sound outside these windows, with whom we have fought through centuries even within the walls of this castle, and from contact with whom we have, through the ages, received so much fruitful inspiration. Now you will realize what a shock I got when, after my address, a member of the audience came up to me and said that he could not understand why I hated the Swedes. Obviously I must have expressed myself most confusingly on that occasion, and I am afraid that also to-day I have talked in a very obscure way. Still, I hope that I have not spoken so obscurely as to give rise to any such misunderstandings of the trend of my argument.

Modern Trends in Air Transport*

MOST modern air transport is by means of the aeroplane, a body heavier than air, depending upon forward movement for sustentation. For purposes of this examination it can be considered to consist of four fundamentally different systems: (1) the lifting system, that is, the wings; (2) the non-lifting system, principally the body, a structure with space for the load, a girder carrying the tail control units, and often the power plant; (3) the propulsive system comprising the engines and airscrews; (4) the control system, including all devices by which the pilot governs the movements of his aircraft. The trend in development of each of these is examined from the point of view of its approach towards air transport ideals of carrying capacity, speed, range, economy, comfort and safety.

The lift of a wing increases with its area, the square of the speed, and, in general, its angle of attack. Increase of lift therefore demands some combination of larger values of these. It must be remembered that carrying capacity is not gross lift; but rather the surplus of the total lift over that necessary to sustain the weight of the structure, engines, etc. Assuming wing structures carrying the same load per unit area, with the same geometry of structure and materials of construction, while the lift will increase as the square of the dimensions, the volume, and consequently the weight, of the wing will increase as

the cube of these. This relationship, known as the square/cube law, implies that with weight increasing at a greater rate than lift, the carrying capacity of any wing system will ultimately be reduced to zero. The functioning of this law is being defeated by designers by the more efficient distribution of the materials in the structure, the use of specifically stronger (strength/weight) materials, and improved aerodynamic design allowing increased speed for the same power, and consequently extra lift from the same wing area. This is further helped by the fact that the power required is a factor of the wing area, and its weight is only increasing as the square of the linear dimensions of the machine. Increase in angle of attack, as a method of obtaining additional lift, results in an increase in drag of the wing at such a rate that the weight of the extra power plant necessary to overcome it soon cancels out its extra lift. As an example, early post-War commercial aeroplanes weighed from three to five thousand pounds with a wing loading of eight to twelve pounds per square foot, and there was evidence that the optimum size under the square/cube law was already approaching. A new Boeing flying boat, now building, will weigh 82,000 lb. with a carrying capacity of 10,000 lb. while some projected designs for trans-ocean services are of 200,000 lb. total weight and expected to carry a pay load of 25,000 lb., with wing loading of 30-40 lb. per square foot.

The question of speeds is one of commercial requirements. They have risen from 50-80 mile per hour to 150-200 miles per hour normal cruising

* Based on a lecture by Prof. W. F. Durand, emeritus professor of mechanical engineering in Stanford University, given at the recent meeting of the American Association for the Advancement of Science, Richmond, Virginia.

speeds, with much higher top speeds when necessary. The probable highest possible speed of flight that can be visualized at present is about 500 miles per hour, assuming a machine with its various characteristics combined in an optimum manner for this alone, a quite impractical proposition in many other respects. Excluding commercial stratosphere flight—as yet unproved—300 miles per hour appears to be about the practicable limit for commercial aircraft.

Range, the distance flown without alighting or refuelling, obviously depends upon an arbitrary balance between paying load and fuel carried. The theoretically maximum range, with no pay load, and neglecting the effect of weather conditions, assuming a machine designed specially for maximum performance in this respect, appears to be of the order of 8,000–9,000 miles. The present record is about 7,000 miles, and it is not unfair to say that the reduction in this figure is largely due to adverse weather conditions and the limitations of the human element in the control of the machine. Economic considerations bring this figure down considerably; the China Clipper flying boats on the Pacific service, making flights necessarily 2,000 miles in length, are not considered to be a paying proposition to-day. It is anticipated that the new 82,500-lb. flying boat, already mentioned, will have an economic range of 2,400 miles at a cruising speed of 150 miles per hour. It is interesting to note that the cost of operating these long-range commercial flights is curiously stable at an average of 2 cents per passenger seat per mile. These performances may also be modified by taking advantage of the reduced resistance of the more rarefied air at high altitudes. Here again record flights on special machines (52,937 ft.) have no commercial significance; but it appears that more economical flight should be possible in the sub-stratosphere between the altitudes of 20,000 ft. and 30,000 ft. Experimental flights at between 15,000 ft. and 20,000 ft. are already being arranged. The two essentials, that of supplying the engine with the necessary oxygen by supercharging it, and providing the air conditions required for the passengers' comfort by enclosing them in a pressure-tight cabin, have already been accomplished. A Boeing No. 307 is being built for sub-stratosphere flight, with a range of 1,000 miles at 180 miles per hour, carrying a pay load of 9,200 lb.

Comfort for passengers is also an economic question, being principally one of the extra size of the body, with its additional drag and weight, the weight of furnishings of the cabin, the number of crew carried, provision of meals en route and more solid walls for sound- and weather-proofing. All of these are being met in a spirit of competition nowadays.

Safety, principally a matter of allowing for certain adverse weather conditions, can best be studied by considering those conditions in groups that affect an aeroplane differently. Structural breakages due to bad design are practically unknown, and failures of the power plant are being rapidly reduced to a negligible quantity. The Diesel type of engine with its simpler carburation, ignition, and less inflammable fuel, is the more attractive from this point of view, although its performance is inferior in some respects. Flying and navigational instruments are available for all needs, including blind flying and landing in fog, although the human element has to be considered in the limitation of the number of operations that any one person can carry out at the same time. Among more recent developments in this respect are an 'echo' altimeter giving the height of the machine above the ground in the immediate vicinity, a static suppressor that eliminates interference in radio communication, and an automatic radio direction finder working with a gyro-pilot. 'Stall' warning devices of various kinds, coupled with aerodynamic improvements in the control of a machine when flying slowly, have done much to reduce the hazards of taking-off and landing.

The autogyro—a rotating-wing aeroplane—and the helicopter—a flying propeller—are two developments that may have special applications because of some peculiarity that they possess; but their inferior performance in competition with the more conventional aeroplane would appear to limit their use for general air transport.

The position with regard to lighter-than-air craft is not so clear at the present time. Experience dictates that some inert gas, of which helium appears to be the only practicable one, must be used, for reducing fire danger. The restricted supply of this, limited to certain parts of the world, is likely to be a serious factor in the development of airships.

Structural failures in airships of the past have been serious, but lessons have been learned from their investigation, and it is claimed that airships could be built to-day with a structural margin of safety at least equal to a modern aeroplane. Airships are also immune from two possible dangers present in heavier-than-air craft: forced landing due to engine failure, and loss of control resulting in a spinning dive.

In conclusion, it is claimed that although practical flight, which came into being with the success of the Wright brothers in 1903, has presented the transport world with new problems by reason of the fact that it functions in an additional third dimension, they have not proved impossible of solution in both the technical and economic point of view.

Pope Pius XI and His Scientific Interests

WITH the lamented death of His Holiness Pope Pius XI on Friday, February 10, the Christian world at large, and the Catholic body in particular, have lost a spiritual leader who will go down in history as a saintly man of courage and character, of kindness and tolerance, of piety and science.

The duties and interests of a Roman Pontiff are manifold in character. As religious head of the Church, he has to keep, to interpret and to defend the doctrinal and moral teachings of Catholicism. The task of the late Pope in this respect was a difficult one, in view of the social theories and practices of certain totalitarian States. Pius XI placed the whole weight of his authority against individual, social and racial persecution.

As temporal sovereign, the Pope has to consider the political and administrative duties of his exalted position. But in spite of the heavy burden these duties involved, Pius XI never failed to show an active interest in science and its advancement; as a student, he was soon to realize the importance of science not only in a world which is obviously actuated by it, but also for the final shaping of one's philosophical and religious knowledge. As a young scholar, as a curator of the Ambrosian, and afterwards of the Vatican Libraries, as a prelate and finally as a Pope, Pius XI was always assisting the peaceful development of the positive sciences in their various fields of application. For he was convinced that there could be no real incompatibility between science and faith.

The Lateran Treaties, which sealed the peace between the Vatican and the Italian State in 1929, gave the Pope the opportunity of showing in a conclusive manner that he was not only the Pope of peace, but also the Pope of scientific progress. Pius XI took a personal interest in the planning, building and reconstruction of the scientific institutions of his miniature but model State. In November 1930 was opened the new central telephone exchange of the Vatican City; in the following February, the new electric power station and the new wireless station were inaugurated.

The Pontiff was particularly proud of the powerful wireless station at Castelgondolfo, his summer residence, in which the late Senator Marconi embodied the latest devices. The experiments, the tests and the first messages transmitted from Castelgondolfo in April 1932, were followed with the greatest interest by the scientific world. In fact, special receiving apparatus had to be supplied to authorities abroad to suit the requirements of

the ultra-short wave station of Castelgondolfo. Catholics in all parts of the world were thus able to hear in their homes the voice of the Pope himself.

The head of the Church was always ready to co-operate with international scientific organizations. A notable event was the official participation of Vatican delegates to the International Congress of Aeronautics in September 1931 at Budapest. The Pope himself was always ready when his other duties allowed him the time to do so, to receive representatives of learned or technical congresses held in Rome.

The work of the Pontifical institutions in Rome proper was followed with active interest by Pius XI. The inauguration of the new buildings of the Gregorian University in November 1930, of the College of the Propagation of Faith in April 1931, of the Art Gallery in October 1932, the collapse of the roof of the Vatican Library and its subsequent reconstruction, and other similar events, gave the Pope many occasions to confirm his support for the achievements of science. The Pope was informed also of the scientific results obtained by the scholars personally in the Pontifical institutions, not only in Rome, but also in the Catholic University of Milan, which has a world-famous school of experimental psychology under Father Gemelli, and in similar institutions abroad.

The crowning example of the Pope's interest in pure science was the reconstitution in 1936 of the Pontifical Academy of Sciences, which is now housed in the Casina Pio IV in the Vatican gardens, through the generosity of Pius XI himself. The Academy, which was known in the past as the Pontificia Accademia dei Nuovi Lincei, now consists of seventy members chosen from among the most distinguished men of science, irrespective of nationality and of religious profession. The British members are Sir Charles Sherrington and Prof. E. T. Whittaker; the late Lord Rutherford was also a member. His Holiness was present himself at the opening of the new Academy in June 1937:

At the inaugural meeting of the Pontifical Academy last year, Pope Pius XI paid a personal tribute to the benefits conferred on mankind by the labours of Marconi, whom he honoured with his friendship, and of Hertz, to whose widow now living in exile at Cambridge His Holiness made a personal gift of £250. Their work, said the Pope, was accompanied by Divine blessing and recalled the words of Schiller: "Soll das Werk den Meister loben, doch der Segen kommt von oben."

PHYSICAL SCIENCES

Radioactivity of Sea Water

THERE still exists considerable uncertainty regarding the amount of radioactive elements present in sea water, the values found by different investigators varying between very wide limits. In general, a few units of 10^{-12} gm. radium per litre is considered a fair average, although occasionally much higher values have been reported. As regards thorium, the estimates are still more uncertain, generally upper limits only of the content being given, whereas with uranium no sufficiently sensitive method for measuring this element existed until quite recently¹.

Since 1934, through collaboration between this Institute, the Institut für Radiumforschung in Vienna and the Kjemisk Institut in Oslo, we have tried to develop accurate methods for measuring the content of the three elements mentioned in sea water.

Uranium has been measured (by its fluorescence in beads of sodium fluoride excited with ultra-violet radiation) in a considerable number of water samples, taken in coastal as well as in mid-ocean waters and at various depths down to several thousand metres. The results show that uranium is a constant component of sea water, varying in proportion with the total salinity. Ocean water of 35 per thousand salinity holds about 2×10^{-6} gm. uranium per litre, or 2×10^{-8} gm. uranium per gm.

Radium measurements have proved much more difficult, since the amount present is only a small fraction of the anticipated value mentioned above. Success was first achieved in 1936, when we started using a *Mitrisreaktion*, precipitating the radium as sulphate together with barium sulphate by adding small quantities of chloride of barium, of a low and accurately measured radium content, to large quantities of sea water. Working on volumes of 25–200 litres of water from the Baltic, the Kattegat, the Skagerrak and the fjords of Bohuslän, taken at depths from the surface down to 600 metres, we found the radium content to vary between 0.03 and 0.2×10^{-12} gm. radium per litre. We are not yet able to state

with certainty to what extent these variations are due to differences in the radium content with locality, depth, salinity and time.

Separate measurements on the radium concentrated in plankton cells, diatoms extracted from about 6,000 cubic metres of surface water during the spring increase, appear to negative the assumption that particulate matter suspended in the water may be responsible for sensible variations in its radium content.

The average value found from these measurements, namely, 0.07×10^{-12} gm. radium per litre, receives further support from measurements on the radium contained in mollusc shells, *Mytilus edulis* and *Ostrea edulis*. The radium-calcium ratio was found to be about 0.2×10^{-12} , which corresponds to a radium content in the water of rather less than 0.1×10^{-12} gm. radium per litre. It seems significant that this radium content is only about one tenth of the equilibrium amount corresponding to the uranium content already stated. It has been suggested by one of us² that this apparent deficiency of radium in the sea may be due to a more or less complete removal from sea water of ionium, the parent element of radium and an isotope of thorium, caused by the large-scale precipitation of iron as ferric hydroxide occurring in the sea, especially in coastal waters.

The very low radium content, say less than 10^{-12} gm. radium per gm. water, shows that sea water is several hundred times poorer in radium even than meteoritic iron. If the high radium content in certain samples of red clay and radiolarian ooze were really due to a precipitation of radioactive elements from the superposed column of water, it would appear more likely to assume ionium to be precipitated with iron than either uranium or radium itself. The implications following from this possibility will be tested by us in the near future.

Also, in our thorium measurements we have found it necessary to use a precipitation method, adding ammonia and ferric chloride (purified from thorium)

to large quantities of sea water, to which ammonium chloride had been added beforehand. The thorium content was found to be certainly less than 10^{-4} gm. thorium per litre and probably less than half that amount. If we assume the removal of thorium from sea water through natural precipitation with iron to be as efficient as the removal of ionium, taking the thorium-uranium ratio in the denuded rocks to be 2:1, we should expect the thorium content in sea water (judging from its uranium content) to be reduced from, say, 4×10^{-4} gm. thorium per litre to one tenth that amount, that is, to 4×10^{-5} gm. thorium per litre, or very probably still further.

A detailed report on our measurements will appear in *Meddelanden från Océanografiska Institutet i Göteborg*.

Since writing this account of our work, our attention has been directed to a paper by R. D. Evans, Arthur F. Kip and E. G. Moberg²; working by different methods and using much smaller quantities of sea water, these investigators have found values for the radium content not much different from those we have found with water of quite different origin.

Physical Evidence for the Division of Heavy Nuclei under Neutron Bombardment

From chemical evidence, Hahn and Strassmann¹ conclude that radioactive barium nuclei (atomic number $Z = 56$) are produced when uranium ($Z = 92$) is bombarded by neutrons. It has been pointed out² that this might be explained as a result of a 'fission' of the uranium nucleus, similar to the division of a droplet into two. The energy liberated in such processes was estimated to be about 200 Mev., both from mass defect considerations and from the repulsion of the two nuclei resulting from the 'fission' process.

If this picture is correct, one would expect fast-moving nuclei, of atomic number about 40-50 and atomic weight 100-150, and up to 100 Mev. energy, to emerge from a layer of uranium bombarded with neutrons. In spite of their high energy, these nuclei should have a range, in air, of a few millimetres only, on account of their high effective charge (estimated to be about 20), which implies very dense ionization. Each such particle should produce a total of about three million ion pairs.

By means of a uranium-lined ionization chamber, connected to a linear amplifier, I have succeeded in demonstrating the occurrence of such bursts of ionization. The amplifier was connected to a thyatron which was biased so as to count only pulses corresponding to at least 5×10^3 ion pairs. About fifteen particles a minute were recorded when 300 mgm. of radium, mixed with beryllium, was placed one centimetre from the uranium lining. No pulses at all were recorded during repeated check runs of several hours total duration when either the neutron source or the uranium lining was removed. With the neutron source at a distance of four centimetres from the uranium lining, surrounding the source with paraffin wax enhanced the effect by a factor of two.

It was checked that the number of pulses depended linearly on the strength of the neutron source; this was done in order to exclude the possibility that the pulses are produced by accidental summation of smaller pulses. When the amplifier was connected to an oscillograph, the large pulses could be seen very distinctly on the background of much smaller pulses due to the alpha particles of the uranium.

By varying the bias of the thyatron, the maximum size of pulses was found to correspond to at least two million ion pairs, or an energy loss of 70 Mev. of the particle within the chamber. Since the longest path of a particle in the chamber was three centimetres and the chamber was filled with hydrogen at atmospheric pressure, the particles must ionize so heavily, in spite of their energy of at least 70 Mev., that they can make two million ion pairs on a path equivalent to 0.8 cm. of air or less. From this it can be estimated that the ionizing particles must have an atomic weight of at least about seventy, assuming a reasonable connexion between atomic weight and effective charge. This seems to be conclusive physical evidence for the breaking up of uranium nuclei into parts of comparable size, as indicated by the experiments of Hahn and Strassmann.

Experiments with thorium instead of uranium gave quite similar results, except that surrounding the neutron source with paraffin did not enhance, but slightly diminished, the effect. This gives evidence in favour of the suggestion³ that also in the case of thorium, some, if not all, of the activities produced by neutron bombardment⁴ should be ascribed to light elements. It should be remembered that no enhancement by paraffin has been found for the activities produced in thorium⁵ (except for one which is isotopic with thorium and is almost certainly produced by simple capture of the neutron).

Prof. Meitner has suggested another interesting experiment. If a metal plate is placed close to a uranium layer bombarded with neutrons, one would expect an active deposit of the light atoms emitted in the 'fission' of the uranium to form on the plate. We hope to carry out such experiments, using the powerful source of neutrons which our high-tension apparatus will soon be able to provide.

The Fundamental Length Introduced by the Theory of the Mesotron (Meson)*

It is well known that the vector theory of the meson¹ contains a fundamental length in the interaction of mesons with protons and neutrons determined by the fact that the mass of the meson appears

* The name 'mesotron' has been suggested by Anderson and Neddermeyer (*NATURE*, 143, 874; 1938) for the new particle found in cosmic radiation with a mass intermediate between that of the electron and proton. It is felt that the 'tr' in this word is redundant, since it does not belong to the Greek root 'meso' for middle; the 'tr' in neutron and electron belong, of course, to the roots 'neutr' and 'electra'. In these circumstances, it seems better to follow the suggestion of Bohr and to use electron to denote particles of electronic mass independently of their charge, and negatron and positron to differentiate between the sign of the charge. It would therefore be more logical and also shorter to call the new particle a meson instead of a mesotron.

explicitly in the denominator of some of the interaction terms. This circumstance has the result that in those elementary processes in which the momentum change is large compared with mc , m being the mass of the meson, the interaction becomes very large, leading to Heisenberg explosions, and to greater divergences in some second-order effects than is the case in radiation theory. This has led Heitler¹ and others to the view that the meson theory in its present form is quite incorrect for meson energies larger than about mc^2 , and Heisenberg² to the position that quantum mechanics is competent to deal accurately with only those elementary processes in which the condition³ due to Wataghin,

$$\left| \left(\frac{E_1 - E_2}{c} \right)^2 - (p_1 - p_2)^2 \right| < \left(\frac{\hbar}{r_0} \right)^2, \quad (1)$$

is satisfied, E and p being the initial and final energy and momenta of a particle concerned in the process, and r_0 a fundamental length of the order $\hbar/mc$. The purpose of this note is to bring forward an argument which, it seems to me, shows first that the limitation of quantum mechanics by the condition (1), if true, cannot be based on the explosions as derivable from the theory of the meson, and secondly, to throw some doubt on (1) itself as a limit to the correctness of quantum mechanics.

The argument runs as follows. Let us consider uncharged mesons⁴ for simplicity, since this changes nothing essential to the argument, and consider the Hamiltonian given in A (49)¹. The interaction (58 a) in this contains terms which become very large when the momentum change of the meson becomes large compared to mc in a suitable Lorenz frame. These terms, which lead to explosions, are due as much to the transverse meson waves as to the longitudinal ones, even in the limit when the proton may be considered to be moving non-relativistically. Further, the critical momentum above which explosions begin to appear becomes lower the smaller m , and becomes vanishingly small when $m \rightarrow 0$.

On the other hand, the exact quantized equations of motion for the meson field derivable from this Hamiltonian (A (14) and (15), with the appropriate simplifications for a neutral meson), namely,

$$G_{\mu\nu} = - \left(\frac{\partial}{\partial x^\mu} U_\nu - \frac{\partial}{\partial x^\nu} U_\mu \right) + \frac{g_2}{\hbar c} \psi + \gamma^\mu \gamma^\nu \tau_3 \psi$$

$$\frac{\partial}{\partial x^\mu} b_\mu = \frac{m^2 c^2}{\hbar^2} U_\nu + \frac{g_1}{\hbar c} \psi + \gamma^\mu \tau_3 \psi$$

go over continuously into the Maxwell equations when $m \rightarrow 0$. But one knows from electrodynamics that although there are circumstances in which the emission of a large number of quanta may be more probable than the emission of a single quantum, as in the so-called 'infra-red catastrophe', this in no way sets a limit to the accuracy of quantum mechanics and does not interfere with the calculation of less probable processes by the methods of perturbation theory. Moreover, it is just those processes where the emission of a large number of quanta is very probable which can be calculated classically.

In view of the above circumstances, we must conclude that the appearance of the fundamental length determined by the mass of the meson in the interaction term in no way sets a limit to the accuracy of quantum mechanics. For example, in the collision of two protons with energy very large compared to mc^2 , the probability becomes large for the simultaneous

emission of a large number of mesons, which is the analogue of the 'infra-red catastrophe' for quanta of finite rest mass, and hence quantum mechanics is none the less competent to deal with it. It can similarly be shown that we can calculate the production of large explosions to a high degree of accuracy by treating the meson field quantities classically, that is, as non-quantized magnitudes, for since mesons satisfy Einstein-Bose statistics, the meson field becomes a classical one just in the case where we are dealing with a large number of mesons.

Hence if a fundamental length r_0 exists which limits the applicability of present quantum mechanics to the cases satisfying (1), this length r_0 has nothing to do with the mass of the meson or the appearance of explosions. Quantum mechanics in its present form cannot be strictly valid since it leads to divergent results connected with the self-energies of point charges; but these limitations are probably due to the fact that it is not the quantization of the correct classical equations for point charges, and not to the existence of a fundamental length r_0 . These equations have only recently been given by Dirac⁵ and their quantization has not yet appeared.

Accordingly, we might expect that very fast protons (or neutrons) would produce explosions consisting of mesons of momenta roughly mc , while mesons with energy much larger than the proton rest-energy would not do so, and their scattering by protons would also decrease with increasing energy, in analogy with the Compton effect.

It can be shown that the classical retarded meson field and potentials due to the world line of a classically moving proton or neutron can be written as the sum of two parts. The first part has exactly the form that the corresponding electromagnetic quantities would have for a point charge and point dipole (represented by a six-vector) moving along a classical world line, and does not contain the mass of the meson. The second part has no singularity at any point of space including the world line of the proton, and goes to zero as the mass of the meson $m \rightarrow 0$. The meson singularities are therefore identical with the electromagnetic singularities, and it is possible to eliminate these to the same degree and in the same way as has been done by Dirac⁶ for the electromagnetic field of a point charge.

The detailed calculations will be published elsewhere.

Magnetism and the Maxwellian Theory

I AM glad to see from Mr. Rollo Appleyard's letter in *NATURE* of December 31 that he is satisfied with my reply to his query concerning the place of magnetism in fundamental electrical theory. Of course there can be no question of "annihilating magnetic notions" in view of the existence and properties of

permanent magnets; but, as regards the understanding of fundamental physical phenomena, magnetism appears to have played a part similar to that of money in economics—a useful link for facilitating exchange, but a source of unnecessary complexity and confusion in discussion. Since we can formulate the forces acting on moving electric charges directly from Ampère's experiments without introducing magnetism, and thereby dispense with the two stages of reasoning involved in Maxwell's curl equations, it seems decidedly advantageous to do so; and if a magnetic field is merely a translationally moving electric field, as the flux-cutting principle suggests, it seems superfluous to regard it as a separate entity.

What we have hitherto called an electromagnetic wave is simply a wave of electric force and displacement, or electric wave, corresponding to the pressure and displacement in an acoustic wave; and the dualistic concept of two waves of electric and magnetic force in perpendicular planes is a superfluous complication. The electrostatic forces between stationary charged bodies and the propagation of electric waves can be illustrated satisfactorily by assuming protons and electrons to be connected by contractile tentacles or bonds, and the only phenomenon which seems unexplainable by mechanical principles is the transverse force on a moving charge caused by the proximity of another moving charge. This is perhaps the most important fundamental problem in physics and may seem to justify the vortical concept of a magnetic field; but this concept does not appear to provide a convincing explanation. We do know, however, from Ampère's experiments, what this force is; and the general formula given in my letter in NATURE of December 3 enables us clearly to understand the behaviour even of dynamos and transformers without any consideration of magnetism.

Mr. Appleyard has, however, raised another important fundamental point by directing attention to the fact that this force as given by the second

term in my equation: $E_2 = \frac{e}{c^2} [V' \cdot \nabla \phi]$, has no

meaning unless the velocities V and V' are defined with respect to a basic framework or medium. This term is in accordance with Maxwell's treatment of moving charged surfaces ("Treatise", 2, xix, § 769); with Ampère's experiments; and with the flux-cutting equations given in my article in NATURE of February 5, 1938. These equations: $E' = [VJ] = \kappa[V \cdot E]$, and $E' = -[VB] = -\mu[VH]$, appear to be the true fundamental equations if the magnetic link is employed, and lead to the relation $E' = \kappa V \cdot E$ for an isotropic dielectric medium if that link is eliminated; but it is evident that they also have no meaning for space unless V is defined relatively to a basic framework or medium; and the physical picture of electric wave propagation which arises from them is so clear and convincing as to leave no room for doubt that electric waves, including light, are undulatory electric displacements in a basic medium or ether which has the properties of a dielectric. I believe that this will be acknowledged in due course, and that the classic theories and concepts of Newton, Faraday and Maxwell will be restored to their rightful eminence.

Ultra-violet Absorption Spectrum and Chemical Reactivity of some Substituted 9-Vinyl-Phenanthrenes

THE direct conjugation between two aromatic nuclei or between an aromatic nucleus and an olefinic double bond expresses itself in the spectrum: diffuse bands appear instead of the sharp ones and at higher wave-lengths (diphenyl¹, di- α -naphthyl², styrene³, etc.). It is therefore worth reporting that 9,9'-diphenanthryl (I), although having a system of two conjugated olefinic double bonds, exhibits a spectrum which is practically identical with that of phenanthrene⁴ (two regions of absorption: persistent, diffuse bands between 2700 and 3000 Å., and sharp bands at higher concentrations, between 3000 and 3500 Å.). The same is true for 9-cyclohexenyl-phenanthrene (II), which does not behave spectroscopically analogously to styrene.

It is interesting that the two hydrocarbons, according to E. and F. Bergmann⁵, do not show any 'dienic' activity, for example, towards maleic anhydride. If there really is a parallel between this inactivity and the spectral behaviour, one would expect that for a substance analogous to (II), but having an active conjugation, the spectrum should show the above-quoted characteristic features. This is actually the case: 9-cyclopentenyl-phenanthrene (III), which easily combines with maleic anhydride, has fewer and markedly more diffuse bands than phenanthrene, at the same time shifted towards the visible part of the spectrum.

A detailed description of our results and a report on other cases of such an unusual coincidence will be given elsewhere.

Atomic Lines in the Auroral Spectrum

PROF. L. VEGARD's recent note¹ on the atomic lines in the auroral spectrum calls for some comments. While it is true that the presence of the Vegard-Kaplan bands in auroral spectra was first observed and interpreted by Vegard, R. Bernarc reported an auroral spectrum in which these bands

and the 3,470 line were unusually strong in comparison with the rest of the spectrum. The remarkable resemblance between this auroral spectrum and the high-pressure afterglow spectrum discovered by me led Bernard to interpret the radiation at 3,470 as a line rather than as the 2 *P.G.* (3-4) band as proposed by Vegard. One must give Bernard credit for an important new observation in recognising this resemblance.

It must be pointed out that Vegard's interpretation of this 3,470 radiation as a nitrogen band is very difficult to understand. As support for this interpretation, Vegard cites the fact that other bands of the progression 2 *P.G.* (3-*n*) appear in the auroral spectrum. These other bands should be much more intense, however, than the band 3469 (3-4), whereas in Vegard's own auroral spectra the 3469 band is the most intense of the three bands 3285 (3-3), 3671 (3-5) and the 3469 band. An examination of any laboratory source of this system will show immediately that this discrepancy will rule out Vegard's explanation and lends support to that proposed by Bernard. Furthermore, the band at 3469 is stronger than the 3500 band in the same sequence. In the large number of afterglow and discharge spectra that have been photographed by me during the last decade, I have never observed such a large enhancement in the intensity of this band as that implied by Vegard. It appears, therefore, that the greater part of the radiation at 3470 is due to the ²*P*-4*S* line, and only a very small fraction to the 3-4 band.

I have also obtained some new spectra which should further help to settle this question. Several years ago¹ I produced the green auroral line in rapidly interrupted weak discharges with remarkably large relative intensity. Accompanying this weak discharge was an afterglow showing an equally remarkable enhancement of the Vegard-Kaplan bands. It was recently possible to duplicate this phenomenon in the high-pressure afterglow. In this case the new nitrogen line (instead of the auroral green line) is so strong that it is at least ten times as intense as the strongest second-positive band. This new experiment leaves no question in my mind as to whether the radiation around 3470 is a band or a new line, and it also adds heavily to the evidence which favours both Bernard's identification as well as my proposal that the line is the transition ²*P*-4*S* in atomic nitrogen.

Photo-sensitive Titanium Dioxide

ATTENTION has already been directed to the reversible darkening in daylight exhibited by some varieties of commercial titanium dioxide¹. Mechanisms for this darkening were suggested and the possibility that the phenomenon is connected with iron present as an impurity in the titania was borne in mind. Titanium dioxide contaminated by iron, which shows rapid reversible darkening in daylight, has been prepared by the following simple process.

Titanium dioxide is mixed with an aqueous solution containing enough iron salts to add 0.2 parts by weight of Fe₂O₃ to 100 parts by weight of TiO₂. The mixture is evaporated to dryness. The residue

is ground for a few minutes and then calcined for three hours to a final temperature of 1,000° C. Calcination is performed in a metallic resistance furnace wherein the titania is freely exposed to air. The resulting readily pulverizable product when ground is ready for study.

The titanium dioxide used in the experiments showed no perceptible darkening in daylight and gave the following spectrographic analysis (prepared by Messrs. Adam Hilger, Ltd.). Ca, trace; Fe, very slight trace; Na, very slight trace, practically 0; P, trace; Pb, minute trace, practically 0; Sb, slight trace; Si, heavy trace; Sn, minute trace. Elements sought with negative result: Ag, Al, As, B, Ba (probably; lines masked), Be, Bi, Cd, Co, Cr, Cu, K, Li, Mg, Mn, Mo, Ni, Sr, Th, Tl, V, W, Zn, Zr.

Iron was added to this oxide as ferrous sulphate or ferric ammonium sulphate, both of analytical reagent quality.

Very precise standardization of quantities or heating schedules is not necessary to obtain striking results. Moreover, there is evidence that certain metals other than iron, used as contaminants, give rise to photo-sensitive preparations.

It is hoped to give a fuller account of the subject of this communication, and of related matters, at a later date in the *Transactions of the British Ceramic Society*.

Migration of Barium on Molybdenum

IN a previous letter¹ we stated that no evidence had been obtained for the surface migration of barium over nickel or tungsten. We have recently published these results² in detail, together with the results of the behaviour of thorium on tungsten.

(a) INITIAL DEPOSIT OF BARIUM OVER PART OF WIRE SURFACE. (b) COMPLETE MIGRATION AROUND WIRE AFTER 20 HOURS AT 1010° K.

The electron microscope described for round wires has been used to study the behaviour of barium on molybdenum. It has been found that over the temperature range of approximately 1,000°-1,050° K., barium migrates uniformly over molybdenum. Below 1,000° K. no movement occurs, and above 1,050° K. evaporation of barium takes place very rapidly.

The two reproductions show the beginning and end of a run at 1,010° K., with barium on molybdenum. It will be noted that the appearance of the migrated layer is similar to that which we have already shown for thorium.

Structure of Proteins

WE have naturally followed with much interest recent developments in the 'cyclol' hypothesis and the structure of the globular proteins¹; but among other things we find difficulty in correlating the following two statements, presumably arrived at by applying the same theory to the same facts: (1) "The properties of proteins shown by our experiments seem to be in accord with the view that the protein monolayer is a two-dimensional network held together by strong elastic springs and are not in accord with a structure consisting of polypeptide chains"²; (2) "This we interpret to mean that, in the formation of monolayers, some or all of the cyclol bonds are opened, few or none of the peptide links being broken, so that protein monolayers consist of polypeptide chains partially or wholly decyclized. . . . This type of structure explains many of their striking characteristics: for example, viscosity, elasticity, etc."²

We ourselves, in view of so much evidence to the contrary, have all along felt that inference (1) was scarcely justified; and in fact we have demonstrated experimentally, by direct measurement and X-ray and optical examination⁴, that egg albumin monolayers deposited by the Blodgett-Langmuir technique do indeed consist of polypeptide chains; but since no references are given and no reason for the change of view from statement (1) to statement (2), it would be helpful to be informed more fully.

⁴ Astbury, W. T., Bell, F. O., Gorter, H., and Van Ormondt, J., NATURE, 143, 33 (1938).

THE facts, which Astbury and Bell ask for, that have led me to believe that the spreading of a globular protein on water involves the breakdown of a cyclol cage molecule into polypeptide chains without open ends, were given by me in detail in a lecture on July 1, 1938, at the Cold Spring Harbor Symposium on Proteins, in the ensuing discussion, and in the discussion of Dr. Wrinch's paper on June 30. Dr. Astbury attended these lectures. The lectures and discussions have been published in the Cold

Spring Harbor Symposia on Quantitative Biology, vol. 6.

The reasons for the opinion were based upon studies of the viscosities, mechanical properties and solubilities of protein monolayers and a comparison with results obtained with monolayers of several well-recognized long-chain polymers. The fibrous structure that can be developed by shear or by unilateral compression in monolayers of egg albumin, edestin and urease were described and given as additional evidence of the presence of chains in the monolayers. These facts were obtained and the lecture was delivered long after the publication of the "first statement" which Astbury and Bell object to, but before the publication of the paper by Astbury, Bell, Gorter and Van Ormondt.

IRVING LANGMUIR.

Bluffing by Eclipse Prediction

THE communication by Prof. W. A. Osborne¹ has the effect of opening up the question whether the eclipse of the sun mentioned by Anna Comnena may be included in 'historical eclipses'. It is interesting to be able to state that her record seems to be quite sound. There was a total eclipse visible at Constantinople on February 16, 1086.

Most of us have obtained the small amount of knowledge we have about the Emperor and his daughter from the Waverley novel, "Count Robert of Paris". Scott for some reason chooses to describe the lady as being twenty-seven years of age, but he must have known that really her age was only fourteen years, at the time of the story, when the crusaders passed through Constantinople. He gives us a very delightful picture of the daughter reading a newly written chapter of her book to her father for his advice and approval; but here again he must have been equally well informed of the fact that she wrote the work after the emperor's death, when she had taken up her residence in a convent. Now we can all say that she must have had access to reliable records, which enabled her to state with assurance that "the whole [of the sun's] disk was darkened". Usually when a solar eclipse is mentioned by these early writers, the words used are so vague that it is impossible to say whether the eclipse was central or partial at any given locality. In the circumstances, some words of congratulation seem to be due to Anna Comnena and to the authorities who compiled the records from which she derived her information.

The total phase occurred at Constantinople about 4.12 p.m. local mean time. The track of the shadow from the Aegean to the Black Sea seems to be as follows:

Longitude	Latitude
24° 23' E.	39° 54' N.
27° 17' E.	41° 5' N.
30° 17' E.	43° 0' N.
34° 6' E.	45° 8' N.

I obtained the data from the catalogue of eclipses in "L'Art de Vérifier les Dates", vol. 1. The calculations are my own.

BIOCHEMISTRY

Coupling between Pyruvic Acid Dehydrogenation and Adenylic Acid Phosphorylation

A new coupling of oxidation-reduction and phosphorylation, with thiamin (vitamin B₁) pyrophosphate as a link of the reaction chain, was found with dry preparations of *Bacterium Delbrückii* (*Acidifactor longissimus*). Phosphorylation of added adenylic acid occurs when pyruvic acid is dehydrogenated, and, as reported previously¹, thiamin pyrophosphate is the prosthetic of the enzyme catalysing the dehydrogenation of pyruvic acid.

When a suspension of certain bacterial preparations, containing very little adenylypyrophosphatase, is shaken with air in the presence of pyruvic and adenylic acid, the oxygen consumption is accompanied by disappearance of inorganic phosphate.

Table 1.

	Initial value	0.125 mol. pyruvate —	0.125 mol. pyruvate 0.03 mol. adenylic acid	— 0.03 mol. adenylic acid
Mgm. inorganic P	0.59	0.53	0.31	0.59
Mgm. ("ml") easily hydrolysed P	0	0.06 (42)	0.23 (200)	0.01
— ml O ₂	—	490	474	58
— P: — O ₂	—	0.04	0.21	—

Aerobic experiment: ca. 25 mgm. dried bacteria, suspended in 0.06 mol. sodium fluoride-phosphate solution, were shaken with air at 37.5° for an hour.

Equation: pyruvate (H₂O) + ½ O₂ = acetate + CO₂ + H₂O.

The organic phosphate compound formed is split by seven minutes hydrolysis with normal hydrochloric acid (see second line of Table 1). Since tests for phosphopyruvic acid were negative, this is taken as evidence for adenosinopolyphosphate synthesis.

As reported elsewhere¹, dismutation is very poor with the dried bacteria, but can be developed by the addition of riboflavin². The analysis showed dismutation to be a fermentation-like reaction with pyruvic acid—pyruvic dehydrogenase as reductant, pyruvic acid—lactic dehydrogenase as oxidant and flavin acting as hydrogen carrier between the two enzymatic systems. The reductant is the same both in aerobic dehydrogenation and in anaerobic dismutation of pyruvic acid. The oxidants, however, are different, being oxygen in the first case and pyruvic acid-lactic dehydrogenase in the second.

It appears from the anaerobic experiment shown in Table 2 that the dismutative reaction also gives rise to phosphorylation.

Table 2.

	Initial value	0.125 mol. pyruvate 0.03 mol. adenylic acid	0.125 mol. pyruvate 0.03 mol. adenylic acid 0.1 mgm. riboflavin
Mgm. inorganic P	0.6	0.59	0.41
Mgm. ("ml") easily hydrolysed P	0	0.01	0.19 (128)
ml CO ₂	—	5	17½
— P: CO ₂	—	—	0.8

Anaerobic experiment: as aerobic experiment, only with nitrogen.
Equation: pyruvate (H₂O) + pyruvate = acetate + CO₂ + lactate.

Since the coupling takes place anaerobically as well as aerobically, it should be independent of the hydrogen acceptor but intimately associated with the dehydrogenation process catalysed by the mediation of thiamin pyrophosphate. In this connexion, it must be considered that inorganic phosphate is an indispensable component of the pyruvic acid dehydrogenation system³. A very close resemblance might exist between the function of the pyridine nucleotide in the coupling reaction in fermentation, analysed by Meyerhof⁴ and by Needham⁵ in detail, and the function of the thiazole derivative in our reaction⁶.

In my opinion, the linkage between the thiamin and adenylic acid systems will prove to be of great importance for the understanding of the metabolic function of thiamin in the living cell. A new source of phosphorylation energy appears which can be utilized both aerobically and possibly anaerobically. The skeletal muscle and to a still greater extent the heart muscle are probably supplied with energy from this source. It is well known that heart failure is one of the most conspicuous symptoms of B₁-avitaminosis⁷ and, according to Birch and Mapeon⁸, the inability of the heart to dispose of free adenylic acid is the cause of the bradycardia of animals deprived of thiamin. Also, the oxidative phosphorylations in kidney and liver, reported by Kalokar⁹, might be linked in part to the thiamin system.

I wish to express my sincere thanks to the Ella Sachs Plotz Foundation for the aid given to this work. The adenylic acid was very kindly supplied to me by Dr. P. Ostern.

Effect of Nicotinic Acid Deficiency on the Coenzyme Content of Tissues

It is now well recognized, largely through the efforts of the Euler and Warburg laboratories, that nicotinic acid amide is a constituent of both coenzyme I and coenzyme II. Since these coenzymes have such an important role in the metabolic processes of the body, it is of decided importance to acquire more information concerning their physiology. A good deal has been learned from studies with synthetic enzyme systems in which these coenzymes are involved. The *in vivo* approach has been attempted by the Euler group. They have confined themselves to rats as the experimental animals and have encountered many obstacles in their work, since it has been very difficult to demonstrate a clear-cut deficiency in the rat of the coenzymes or of any of their possible precursors. Recently, however, Elvehjem and co-workers¹ have demonstrated a

definite nicotinic acid deficiency in the dog, and Dr. H. Chick *et al.*¹ have made similar observations on the pig. We have thus been enabled to work with two different species in which a definite nicotinic acid deficiency is relatively easy to produce.

Our first approach was an attempt to demonstrate a decrease in the coxymase content of the blood of dogs deficient in nicotinic acid. The coxymase was determined by Euler's method², and every analysis was strictly controlled with blood from a normal animal. In no case were we able to find any differences between the coxymase content of the bloods drawn before and after nicotinic acid therapy. Similar results were obtained by analyses on the blood of deficient pigs.

Our next approach was the coxymase analysis of the brain, liver, kidney and muscle of two pigs and one dog, all showing a definite nicotinic acid deficiency. These analyses were also controlled by using for comparison similar tissues from animals fed the basal diet plus nicotinic acid. The following results were obtained:

(a) There was no decrease in the coxymase contents of either the brain or kidney.

(b) The livers of the deficient animals showed a decrease of about one hundred per cent, while the muscles showed a decrease of so high as one thousand per cent, in their coxymase content.

The accompanying table summarizes the results obtained from the coxymase analyses of normal tissues:

Tissue	Coxymase* (mgm./100 gm. fresh tissue)	Nicotinic acid amide (calc.) (mgm./100 gm. fresh tissue)
Beef muscle	31	5.7
Beef liver	70	12.9
Pig liver	52	9.6

The coxymase values agree with those found by Ochoa³ for rabbit muscle.

The calculated nicotinic acid amide values are of necessity minimal since the coxymase determination includes neither the free acid or amide, nor coenzyme II. The above values for the amide agree in a general way with the nicotinic acid equivalence obtained by bio-assay on the same tissues⁴, and also with those from actual isolation when expected losses are taken into consideration^{5,6}. Karrer⁷, on the other hand, reports values for nicotinic acid amide which are so low that they cannot begin to account for the coxymase alone which is present in the tissues.

It is evident that the coxymase content of the tissues of normal animals remains quite constant, while in a nicotinic acid deficiency there is a decided decrease in the coxymase content of both the liver and the muscle.

Inactivation of Progesterone in the Organism

SOME years ago, I was able to demonstrate that oestrone which had been administered to the organism very soon became inactive¹. Mature mice or infantile rats were injected subcutaneously with large doses of oestrone (up to 40,000 M.U.). Three to seventy-two hours after the administration of the hormone the animals were killed, cut into small pieces and extracted *in toto* with an organic solvent. It was apparent that even after a very short time, only very insignificant amounts of the hormone (about 1 per cent) could be detected. There remained, indeed, always a certain quantity of active hormone, sufficient to produce oestrus; but the question whether we were considering a hormone which had not become inactive, or one which had become re-activated again, could not be decided. Oestrone is inactivated in the liver, probably by means of an enzymatic process. This inactivation, apparently, is a general biological reaction, since it takes place not only in warm-blooded, but also in cold-blooded animals and in plants as well.

Similar experiments have now been carried out by means of progesterone. For each experiment (progesterone of Organon-Oes was used) two infantile rats were injected subcutaneously with 2.5 mgm. (= 2.5 rabbit units) respectively of progesterone. (An infantile rat tolerates at the most 3.5 mgm. of progesterone.) Forty-eight hours after hormonal treatment the rats were killed, cut into small pieces and ground, including the fur, until a fine mash of tissue resulted. To begin with, this mash was extracted with acetone for some days at room temperature until a fine dry powder was obtained. This was then thoroughly extracted with alcohol and ether for twenty hours in a Soxhlet. All the residue was collected (acetone, ether and alcohol) and only that part which was soluble in absolute alcohol was used. This was dissolved in 10 c.c. of oil (solution A) and tested for its content of progesterone (+) in infantile rabbits. For eight days preliminary treatment with 20 M.U. of oestrone respectively was given, after which the rabbits were given daily 2 c.c. of the oily solution A during the course of five days. On the fourteenth day the animals were killed and the uterus subjected to histological examination. The presence of the decidual transformation of the uterine mucosa proves that at least 1 rabbit unit (= 1 mgm.) must be present in the extract. The experiments having been set up with 5 mgm., the results furnished proof of the fact that 20 per cent of the progesterone which had been administered is still present in the bodies of the rats.

Administration of progesterone	Time elapsed before extraction (hours)	Progesterone transformation is present, that is, 1 mgm. has been detected = 20 per cent
5 mgm.	6	+++
5 mgm.	12	+++
5 mgm.	24	++
5 mgm.	48	—
5 mgm.	96	—

As shown by the accompanying table, the experiments demonstrate: (a) that 6 and 12 hours after the administration of progesterone at least 20 per cent of the hormone could be detected in the organism; (b) that 24 hours after the administration of the hormone the decidual reaction was inadequate, that is, scarcely 20 per cent was still present; (c) that 48 hours after the administration of the hormone the decidual reaction was negative and that there was, therefore, no longer 20 per cent.

Although the progesterone reaction, that is, the decidual transformation of the uterine mucosa, does not occur until about 100 hours have elapsed, even after 48 hours the hormone is no longer present in an active form. In this respect, progesterone is similar qualitatively to oestrone. Inactivation of oestrone, however, occurs much more rapidly and much more intensely than that of progesterone.

Control experiments were set up to prove that, with the help of the extractive method, progesterone which had been added to the mash could again be proved quantitatively.

Determination of rH in Endocrine Extracts of a Protein Nature

We have begun to study systematically extracts of endocrine glands containing hormones of a protein nature, especially extracts of the anterior pituitary lobe (ALH) of cattle. For technical reasons very dilute extracts were used: 1 gm. of the dry powder, previously kept *in vacuo*, was shaken for 4 hours with 20 ml. of a 0.0001 *N* NH_4Cl solution and then filtered. The pH of the filtrate was kept at about 6.2.

Search was made for reducible substances in the solution and their reduction potentials were measured by means of Heyrovsky's polarographic apparatus with the dropping mercury cathode. All measurements were made with a voltage of 3 volts across the potentiometer. Before each experiment a stream of electrolytic hydrogen, thoroughly purified, was bubbled through the solution. The sensitivity used was generally 1/50 and 1/100 of the total sensitivity of the galvanometer.

We show first the current voltage curve obtained with an extract of powdered ALH, showing three steps corresponding with three reducible substances (groups), having well-defined reduction potentials: $rH_1 = -0.23$ volts, $rH_2 = -1.00$ volts, $rH_3 = -1.65$ volts. The second decimal figure has no great significance.

These three steps did not appear when the powder had not been kept *in vacuo*; they disappeared gradually as the extract was made more and more alkaline, and completely at pH 9.9. These substances (groups) are soluble in ether and in acetone. We were able to repeat these results with powders made from different fresh or frozen glands or glands kept for a time under acetone and also with different extracts prepared from the same gland.

Next, we wished to establish whether the three rH values corresponded with different anterior pituitary hormones. We first examined several purified commercial preparations. One of them had, as shown by tests on guinea pigs and rats, a thyreotropic and a gonadotropic action. This preparation, diluted with 0.0001 *N* NH_4Cl , showed reduction potentials at $rH = -0.23$ v. and $rH = -1.65$ v., and therefore corresponds with rH_1 and rH_3 of the total extract of the powdered ALH. Another preparation showed in our own tests a gonadotropic action, but no signs of thyreotropic activity, as determined by the usual guinea pig method. This preparation

showed $rH = -0.23$ v. and sometimes $rH = -1.00$ v. and therefore corresponded with rH_1 and rH_2 of the total extract.

Finally, we ourselves prepared extracts from the powdered ALH. One extract showed a gonadotropic action, but no definite thyreotropic effect or only very little. It had a reduction potential of $rH = -0.23$ v. only.

Another extract prepared by us showed some thyreotropic but no gonadotropic action and a reduction potential of $rH = -1.65$ v.; it therefore corresponded with rH_3 of the total extract.

CURRENT VOLTAGE CURVE OF A TOTAL EXTRACT OF POWDERED ALH. ABSCISSA: VOLTAGE, ONE DIVISION = -0.15 VOLTS. ORDINATE: INTENSITY OF THE CURRENT. UPPER CURVE: SENSITIVITY 1/50 (ORDINATE: 1 MM. = 2×10^{-7} AMP.). LOWER CURVE SENSITIVITY 1/100 (ORDINATE: 1 MM. = 1×10^{-7} AMP.).

We were not able to find these two substances ($rH = -0.23$ v. and $rH = -1.65$ v.) in extracts from other glands. There are, of course, reducible substances in such extracts; thus we found in some extracts from freshly prepared powdered ovaries from cows rH values of -0.17 v. and -1.35 v., but never values of -0.23 v. or -1.65 v.

The substance (or group of substances) characterized by $rH = -1.00$ v., the rH_2 of the total extract of the powdered ALH, described above, was also found in extracts of the pituitary posterior lobe, whether these extracts had both a hypertensive and an oxytocic effect, or only either of these effects alone.

We conclude from these experiments that in extracts from the freshly prepared powdered anterior lobe of the pituitary the gonadotropic hormone is always accompanied by a reducible group of $rH = -0.23$ v. and the thyreotropic hormone by a reducible group of $rH = -1.65$ v. Gonadotropic hormone prepared from urine of pregnant women does not contain this reducible group having an rH of -0.23 v. The physiological significance of these two specific reducible substances (groups) remains still to be investigated.

Trimethylamine Formation in Relation to the Viable Bacterial Population of Spoiling Fish Muscle

IN view of the recent communication in *NATURE* on this subject¹, the following comments may be of interest.

Experiments with haddocks stowed in ice² have shown that there is no close correlation between the viable count and the trimethylamine content of the flesh. Indeed, the content of dimethylamine, also produced from trimethylamine oxide, follows the general curve of bacterial growth much more closely³. Whilst it is most probably true that only certain organisms are capable of reducing the oxide, the empirical fact remains that in haddocks stowed in ice—the usual industrial preservative—the increase in content of trimethylamine has always been found to follow the organoleptic phases of spoilage in a sufficiently consistent way to render the amount of this substance present a useful index of the extent of spoilage. It would seem that, as Dr. Tarr suggests may be the case, the proportion of trimethylamine-forming to non-trimethylamine-forming bacteria is fairly constant, at least under the conditions of stowage mentioned above. The content of dimethylamine has similarly been found to be a useful index of spoilage. Indeed, reference to these two indexes together serves satisfactorily to characterize the condition of haddocks at any stage right up to the point of definite staleness.

Finally, whilst it is reasonable to assume, until the contrary is proved, that the flora of the external surfaces of all sea fish is much the same, it has been found that spoilage may pursue different courses in different species. Thus in the dogfish the contents of diamine and triamine never rise during stowage in ice to the extent that might be expected from the much larger amount of oxide present as compared with the haddock. Indeed, diamine is present only in traces during stowage for thirty days; whilst the amount of triamine is only of the same order as that found under similar conditions in the haddock. The explanation of these results may be that the large amount of ammonia formed from urea, present in much larger amounts in the dogfish than in the haddock, causes the trimethylamine oxide reducers to be overgrown by other bacteria. Certainly it has been noticed that after stowage the flora of the dogfish is considerably restricted in types as compared with that of the haddock.

In this connexion, it is of interest that Dr. Tarr's work, as reported¹, was done with smoked fish, since it is probable that the constituents of smoke effect considerable alteration in the original flora of the fish.

Determination of Uronic Groups in Polysaccharides

URONIC groupings occurring in polysaccharides are usually determined by measuring the evolution of carbon dioxide on heating with 12 per cent hydrochloric acid. Campbell, Hirst and Young¹ have pointed out that a small amount of carbon dioxide is liberated under these conditions from a number of pure sugars and polysaccharides in which the presence of uronic groups is not presumed, though not necessarily disproved. The evolution of carbon dioxide from certain acids that might be formed by

the degradation of polyuronides was reported by Norman and Martin². In an investigation of plant celluloses carried out two to three years ago at the Rothamsted Experimental Station, it was sought to establish whether the carboxyl groups demonstrably present were of the uronic type. Yields of carbon dioxide of the order of 0.2–0.3 per cent were considered to be unreliable for the reason just given, and accordingly recourse was had to the determination of the rate of evolution of carbon dioxide from such substances under standard conditions in the hope that this might be employed for demonstrating the presence or absence of uronic groups. No absolute value is involved inasmuch as it is the rate of absorption that is measured, and this is in part a characteristic of the size of apparatus in relation to the sample, the air stream, and absorbing device employed. The oil bath temperature was maintained at 140°, and a constant rate of aeration secured. The distillation was not carried out in an atmosphere of nitrogen; nevertheless the total yields of carbon dioxide from pure substances were not higher than those given by Campbell, Hirst and Young¹.

Heating was ordinarily continued for five hours, and the absorbing vessels changed every ten minutes in the first hour, every fifteen minutes in the second hour, and thereafter at thirty-minute intervals.

The rate of evolution of carbon dioxide from substances predominantly of a polyuronic nature, such as pectin, was found to be characteristic. The curve for mgm. carbon dioxide evolved per minute per gram exhibited a sharp peak between 20 and 30 minutes from time of reaching the boil. By the end of the first hour, slightly less than 50 per cent of the total carbon dioxide yield was collected. The only sugars exhibiting a sharp peak in carbon dioxide evolution were fructose and sucrose, and in these the maximum occurred earlier, between 10 and 20 minutes from time of boiling. No such sharp maximum was obtained with glucose, from which carbon dioxide was liberated only slowly. Evolution was higher in the second hour of boiling than the first, and the peak, which was ill-defined, appeared to occur at about 75 minutes. By the end of the first hour only about 15 per cent of the total carbon dioxide yield was obtained. The total yield was, in fact, difficult to establish since small quantities continued to be evolved for many hours.

The curve obtained for rice starch was of the same type as that for glucose, but that for cotton cellulose exhibited a peak in the neighbourhood of 30 minutes followed by a steady but not abrupt fall. This was more marked in a sample of Canadian spruce cellulose (not dried), which showed a second but smaller maximum at about 75 minutes. The nature of the curves was such as to suggest that they combined the effect of the uronic grouping in giving an early peak, and that of the hexose material in providing a longer and more steady evolution of carbon dioxide. Such a procedure may therefore be helpful in pointing to the probable presence of uronic groups in polysaccharides, when small quantities only are present. In addition, the total carbon dioxide evolution from a number of plant celluloses was determined.

PERCENTAGE CARBON DIOXIDE EVOLVED FROM CERTAIN CARBOHYDRATES

		Celluloses from:	
Glucose	0.19	Wheat straw	0.30
Fructose	0.50	Rye grass	0.31
Sucrose	0.54	Oak	0.54
Rice starch	0.30	Canadian spruce	0.41
Potato starch	0.30	Jute	0.78
Cotton oxycellulose	1.29	Hemp	0.30
Barbado cellulose	0.18	Manilla hemp	0.55

In support of the conclusion that the presence of uronic groupings could be inferred from the rate of evolution of carbon dioxide, it was further established that the plant celluloses were not homogeneous with respect to groupings giving rise to carbon dioxide, and that mild acid and alkaline treatments effected a reduction in carbon dioxide yield out of all proportion to loss of weight. The following figures were obtained for Canadian spruce cellulose (carbon dioxide yield = 0.41 per cent).

(1) Residue after extraction with hot 5 per cent sulphuric acid for 1 hour, 87.34 per cent; carbon dioxide yield, 0.26 per cent.

(2) Residue after extraction with cold 4 per cent caustic soda for 2 hours, 86.40 per cent; carbon dioxide yield, 0.23 per cent.

Carbon dioxide yield on original basis from (1) = 0.22 per cent. Carbon dioxide yield on original basis from (2) = 0.20 per cent.

While no quantitative significance in terms of uronic content can be attached to very small yields of carbon dioxide from polysaccharides, the development of the procedure outlined above may permit of the demonstration of the presence of uronic groupings with a reasonable degree of certainty.

A Rapid Visual Test for Vitamin A Deficiency

A RAPID visual test for vitamin A deficiency has been described by Gridgeman and Wilkinson¹, by Haines², and recently by Pett³. In this method the patient is first asked to view a strong light (of intensity I), for a standard time T . Then this light is suddenly switched off and the time t required to see a dim light of intensity i is noted. An excessively high value of t is taken to indicate abnormality.

For the past six months I have been studying this method with the view of finding a standard method which will: (a) give maximum discrimination between normals and abnormals; (b) be applicable to uneducated people and children; (c) be capable of being rapidly carried out by an unskilled observer.

The most important difficulty is due to the fact that the time t can be largely influenced by factors such as intelligence, education and nervousness, as well as by vitamin A deficiency.

From my results it appears that: (a) if the intensity I is greater than about 100 foot-candles, the patient closes the eyes or is troubled with after-image; (b) to bring the eye to a definite state and to give maximum discrimination, T must be at least 150 seconds.

Since some time must be spent in making the patient accustomed to the apparatus, I do not think that a reliable indication can be obtained in less than five minutes. At present I make three tests with values of T at 30, 60, 150 sec. respectively, the total time being 7 minutes. The first two serve to make the patient accustomed to the apparatus. Also an abnormal, in addition to showing a long time (t) on the last test, usually shows a considerable difference between the second and third tests. Unintelligent or nervous normals, on the other hand, may improve between the second and third tests.

The patient has to say which of four letters he sees (N , Z , T , X). The letters are about two inches high and are viewed from 18 inches. Objects of similar size are used for children and illiterates, so that ordinary errors of vision do not affect the result.

This work is being continued by Miss E. J. Power-Steele, by whom the detailed results will be published.

A Specific Factor in Extracts of the Choroid Plexus Influencing the Permeability of the Myelencephalic Roof

WE have shown in earlier experiments that in chick embryos the spread of cerebrospinal fluid from the neural canal to the periaxial spaces is coincident with the development of the choroid plexuses¹, and that in rabbit, rat and guinea pig embryos, extra-cerebral spread of cerebrospinal fluid can be induced when a hypertonic saline solution is injected into the blood stream only after the choroid plexuses are differentiated².

In recent experiments we have shown that extracts of the choroid plexus of the rabbit, dog, cow, sheep and guinea pig contain a factor which has the following properties:

(1) It increases the intradermal spread of dyes to a degree commensurate with that of the spreading factor isolated from mammalian testis by McClean³ and investigated by Hoffman and Duran-Reynals, Claude and Duran-Reynals and others.

(2) It is species specific, that is, the choroid plexus extract of rabbit gives in the rabbit a much wider dermal spread than the choroid plexus extracts of cow, sheep and dog; the choroid plexus extract of the dog produces its most extensive spread in the dog.

(3) Stale extracts are usually less potent than fresh extracts.

(4) By injecting chicken choroid plexus extract into the central canal of the nervous system we were able to anticipate the peri-pariaxial spread of cerebrospinal fluid. In non-injected chick embryos, the first extra-cerebral spread of fluid is seen at 7 days through the anterior membranous area of the myelencephalic roof, coincident with the development of the choroid plexus in the lateral and third ventricles. In injected chick embryos there was a quite marked extra-cerebral spread at five days, that is, two days earlier than the appearance of the choroid plexus, and a slight spread was observed in four-day embryos. Cow choroid plexus and rabbit testis extracts increased the permeability of the membranous areas but slightly and at a much later stage (5½ days).

These experiments suggest that a primary function of the glandular epithelium of the choroid plexus is to elaborate a factor which renders permeable the membranous areas of the myelencephalic roof and thus initiates the extra-cerebral escape of the fluid from the central canal.

We have found recently that extracts of the ciliary body contain a similar spreading factor, an observation which might throw light on the etiology of senile glaucoma.

BIOLOGY

'Sporangial Drops' in the Mucoraceae

It is remarkable that such a commonplace occurrence as the natural liberation of the spores from a sporangium of *Mucor* seems not yet to have been accurately described.

The text-books either ignore the matter, or state briefly that the sporangial wall bursts, setting free the spores. Many of the figures published^{1,2} show

At this stage the spores may be dispersed by contact with solid objects. Comparison may be made with the 'oidial drops' of *Coprinus* described by Brodia³, but a similar function in relation to dispersal by flies has not been observed in the Mucoraceae. Where the 'sporangial drops' come in contact with aerial hyphae, they tend to run down them and collect as large irregular spore-containing drops at points where a number of hyphae touch. Such sporangial and spore-containing drops occur in every culture in which sporangia develop to maturity; but all those observed by me have dried down into solid masses of spores firmly stuck together (Figs. 4-6). The precise conditions under which spores are distributed into the air have not yet been determined, but there is no evidence that in any of the species examined the spores are so dispersed while the sporangiophore is still turgid.

The expansion and contraction of the liquid contents of the unseptate mycelium in response to variations in temperature cause rapid changes in the size of the sporangial drops and the turgidity of the sporangiophores. Even in a sealed cell containing a water surface, sporangiophores and other aerial hyphae are in constant motion owing to slight temperature changes. Thus the stalk of a mature sporangium collapses, as shown in Fig. 2, after a slight fall in temperature, but regains turgidity, as in Fig. 3, when the temperature rises again. This factor is also of some importance in connexion with the growth and bursting of the sporangia.

Fig. 1 ($\times 275$).

Diceranophora fulva SCHBÖT., A SPORANGIAL DROP.

Figs. 2-6 ($\times 437$).

Mucor hiemalis WHEIM. 2, 3, MATURE SPORANGIA WITH (2) COLLAPSED, (3) TURGID, STALK; 4-6, A SERIES TAKEN AT 20 MIN. INTERVALS, SHOWING A SPORANGIAL DROP DRYING DOWN TO A SPORE MASS OF IRREGULAR OUTLINE.

spores apparently being liberated into the air from the end of an erect and turgid sporangiophore, and there is one familiar drawing by Brefeld⁴ which has been described, in at least three books^{5,6} which have reprinted it, as of a sporangium shedding its spores. Reference to the original work, however, shows that the drawing is of a sporangium which has been crushed and treated with alcohol.

Normally, sporangia which burst in mid-air can be watched only under a low power of the microscope, as those which are within range of a $\frac{1}{4}$ in. objective almost invariably burst against the coverslip, the spores flowing out and adhering to the glass around the columella somewhat as shown in Brefeld's figure.

The conclusions I have reached after observations on the sporangia of eight species of Mucoraceae are that, when the sporangium bursts in air and away from any solid surface, the spores are not set free when the wall breaks, nor for some time afterwards. The sporangial wall is replaced by a water surface, and the sporangium becomes a 'sporangial drop' of liquid containing the spores and columella (Fig. 1).

Excretion of Nitrogen by Leguminous Plants

THE results of Virtanen¹ and his associates, concerning the possible excretion of nitrogenous compounds from legumes and their absorption by associated non-legumes, have not in general been confirmed. The investigations of Wilson², Bond³ and ourselves⁴ have

on the whole brought forward evidence contrary to that of Virtanen.

It may be generally assumed that the excretion and donation obtained by Virtanen are associated with some environmental factors not readily reproducible elsewhere.

In more recent experiments carried out at the Waite Institute, attempts have been made to grow peas and oats in association under a variety of conditions, which included variations in the amount of daylight and in the moisture content of the soil. It might be assumed that a reduction in the amount of photosynthesis in a well-established leguminous plant might result in an accumulation of nitrogen compounds above the needs of the plant, such excess being excreted and made available for any associated non-legume.

In these experiments in a series of pots, a mixture of oats and inoculated peas and oats alone were grown in pure sand under favourable conditions for a period of six weeks—the peas at the end of this period were vigorous and healthy. A differential treatment was then imposed for a further six weeks on half of the pots. These pots were allowed two hours of daylight only each day, between the hours of noon and 2 p.m. The atmospheric conditions favoured high transpiration.

Each pot contained either two oat plants alone or two oat plants and two pea plants.

TOTAL NITROGEN (MGM.) IN OAT PLANTS PER POT.

Replicate	Normal daylight, approx. 11 hours daily		Reduced daylight 2 hours daily		Mean
	Oats alone	Oats with	Oats alone	Oats with	
1	4.00	3.83	5.01	7.10	5.01
2	3.91	3.14	5.06	6.84	4.99
Mean	4.00	3.48	5.34	6.97	4.95

The standard error of a single observation is ± 0.35 .

The increases in the total nitrogen content of the oats brought about by shading or by association with peas are independently significant, statistically. The legume effect is significant when the effect of shading upon the oats alone is eliminated.

In no circumstances have we ever been able to obtain evidence of donation in controlled pot experiments under the normal growing conditions in Adelaide. It is of interest that we have been able to obtain evidence of apparent donation by some modification of the local environment.

Respiration Changes following Irradiation with X-rays

In a study of respiratory changes prior to tumour formation after irradiation with X-rays, two disturbances in the oxidation processes of the affected tissues were observed. A group of sixteen mice were given local treatment of X-rays sufficient to produce a burn. At various intervals after irradiation (3 hours-60 days), mice were successively sacrificed and the respiration of the irradiated area compared to the respiration of an

equal control area on the same mouse. It was observed that, after the first day of irradiation, the respiration began to decrease, reaching a maximum depression, after about two weeks, of 60 per cent below the respiration of the control skin. Directly following this period of inhibition was a period of stimulation which brought the oxygen consumption of the irradiated area of skin about 35 per cent above that of the control. This stimulation continued over a period of about five weeks.

It has not been determined at this time whether the initial decrease in oxygen consumption is due to a degeneration and dying of the irradiated cells, and the subsequent stimulation of respiration due to an invasion of leucocytes and new tissue cells, or whether irradiation has more directly altered the respiratory mechanism of the cells.

These results are of particular interest in view of the experiments of Davis¹, which show that the resistance or susceptibility of animals to cancer is dependent upon the respiration of the normal tissues of these animals. There also remains the possibility that a relationship exists between tissue respiration and lymphocytic invasion; for it has been demonstrated by Murphy *et al.*², that when lymphocytosis is prevented by proper dosages of X-rays, the resistant state is abolished. Erythema doses (Murphy³), however, considerably reduce the percentage of 'takes' of autografts.

The fact that X-rays can both stimulate and depress tissue respiration may explain why X-rays can both decrease and increase the resistance of animals to transplantable tumours.

Induction of Polyploidy by Pulp and Disintegrating Tissues from *Colchicum* sp.

INVESTIGATIONS of the active agents in Nature inducing chromosome alterations have shown that the most effective ones are abnormal temperatures¹ and obviously various parasites (cynipid wasps², nematodes³, *Eryophyes*⁴, *Tetranychus*⁵, bacteria⁶, fungi⁷, viruses⁸, etc.). The latter induce abnormalities in the mitotic and meiotic processes chiefly by introducing various substances and partly by wounding, which further give rise to plants with altered chromosome complexes (including polyploidy⁹).

This type of work in connection with the induction of chromosome alterations (chiefly polyploidy) by the alkaloid colchicine⁹ obtained from *Colchicum autumnale* suggested the following experiments: (1) Does pulp from *Colchicum* bulbs induce chromosome alterations? (2) Do disintegrating pieces from the bulbs induce chromosome alterations and particularly polyploidy in seedlings from germinating seeds in the neighbourhood? Experiments performed showed that about two grams of pulp from *Colchicum* sp. bulb induced swellings (like low concentrations from colchicine-induced) in seedlings when seeds from *Triticum*, *Secale* and *Crepis* were germinating on the

pulp, covered with filter paper in Petri dishes. The seedlings that developed at a distance of 1.5–2.5 cm. from the pulp in the dishes showed similar symptoms. Morphologically abnormal seedlings had cells and group of cells with altered chromosome sets (chiefly polyploid) like the seedlings treated with colchicine³. Seeds germinating on disintegrating pieces of bulb from *Colchicum* sp. or near them showed the same morphological abnormalities, namely swelling of the roots and the stems. They also had polyploid cells and tissues. Morphological abnormalities and chromosome alterations (chiefly polyploidy) were also induced when seeds were grown in *Colchicum* pulp

(a) IN THE MIDDLE—A NORMAL (CONTROL) ROOT FROM A WHEAT SEEDLING; ON EACH SIDE, ROOTS FROM SEEDLINGS GROWN (LEFT) ON *Colchicum* PULP AND (RIGHT) AT A DISTANCE OF ABOUT 2 CM. FROM THE PULP IN PETRI DISH WITH FILTER PAPER. (b) RIGHT, A NORMAL WHEAT SEEDLING; THE OTHER TWO, GROWN ON PULP FROM *Colchicum*.

mixed with sand in pots or on disintegrating pieces of various size from *Colchicum* in pots with soil and sand. These observations show that: (1) Pulp from *Colchicum* bulbs can be used for experimental production of polyploid plants. (2) Disintegrating bulbs from *Colchicum* inducing chromosome alterations in laboratory conditions should also cause the same phenomenon in Nature.

The foregoing investigations suggest searching for polyploid forms among the plant species living in Nature together with *Colchicum*.

a culture will die out if it is not provided with fresh tissue by means of subculture. The sarcoma cells infiltrate the added tissue fragment within which they remain for a time embedded. If normal tissue is regularly added, the sarcoma cells can be cultured over an unlimited period and will retain their malignancy.

Since A. Fischer succeeded in culturing sarcoma tissue by the addition of dead tissue (kept in 'Tyrode' in the refrigerator for a month), it might be assumed that the added tissue has a mechanical and perhaps nutritive function in the cultivation of sarcoma, and that the growth of sarcoma *in vitro* depends solely on the continuous multiplication of the original malignant cells. On the other hand, the early experiments of A. Carrel¹ and those recently published by Ludford² show that the Rous sarcoma agent as such is capable of 'infecting' normal cells *in vitro*. We therefore felt justified in assuming that in *in vitro* cultivation of sarcoma according to the methods described above, some process may be taking place in addition to the multiplication of the original sarcoma cells. It may be assumed that the normal cell material which is added is influenced by the agent present in the original sarcoma culture and as a result there is, in addition to a multiplication of sarcoma cells, a constant process of 'cancerization' of the newly added normal tissue.

The first essential in the clearing up of this problem experimentally is the definite separation in culture of agent from the multiplying sarcoma cells. We have succeeded in separating agent from living cells *in vitro* by irradiating cultures with radium.

The relationship between the dose needed to kill cells and that needed to destroy the agent in Rous sarcoma cultures was established accurately. It was, therefore, possible to kill the cells without appreciably impairing the activity of the agent.

An eight-year-old Rous culture strain given us by A. Fischer was used for the experiments. A radium plate containing 6 mgm. of radium was employed, the β -rays being used^{3,4}.

The experiments have shown that the addition of a fragment of tissue or of a pure culture of normal fibroblasts to an irradiated culture of Rous sarcoma, which had received double the dose needed to kill the cells (under the conditions of our experiments this involves an irradiation time of seventy-two hours), results in an invasion of the normal cells by the still active agent. On subculture in a hanging-drop, such a cell colony carrying agent acquires all the known morphological and physiological properties of a real Rous sarcoma culture (typical cell forms, autolytic power, typical behaviour with added cell material). Inoculation into a fowl always proves such a culture to be malignant, causing a typical sarcoma. The use of strongly irradiated cultures causes the 'cancerizing' process to last longer, and the transformation of normal cell colonies in Rous sarcoma cultures manifests itself only after 6–8 passages.

Details of our work will shortly appear elsewhere.

Transformation *in vitro* of Cultures of Normal Cells Treated with Rous Sarcoma Agent into Sarcoma Cultures

THE procedure adopted for the cultivation of the Rous sarcoma *in vitro* in accordance with the usual method described by A. Fischer¹ is as follows: A fragment of tumour is incubated in a medium consisting of chicken plasma and dilute embryonic extract. After a time the growing culture begins to digest the surrounding medium and also itself. Such

Epidemiology of Yellow Fever

URBAN outbreaks of yellow fever are brought to an end either by the eradication of the mosquito vector, *Aedes (Stegomyia) aegypti*, or by the immunisation of a high percentage of the human population. Rural outbreaks are less easily controlled, for in yellow fever areas both in Africa and South America 20-25 per cent of wild monkeys are found to possess immune bodies to yellow fever; in South America, in addition, the so-called jungle yellow fever is transmitted by non-domestic forest-living mosquitoes. Although mosquitoes once capable of transmitting yellow fever by bite appear to remain infective, their life span is short and they are unable to transfer the virus to other mosquitoes either by contact or hereditarily through the egg. If the mosquito-man and mosquito-monkey cycle of transmission represents the complete epidemiological picture of yellow fever, it is not easy to account for the persistence of infection in rural areas during dry seasons when adult mosquitoes are either absent or are present only in very small numbers. It has therefore been suggested that other arthropods may possibly harbour the yellow fever virus, such arthropod vectors either having a longer life than seditious mosquitoes or being able to transmit the virus hereditarily. So far, no biting arthropods other than mosquitoes have been found of importance in the epidemiology of yellow fever.

Two recent observations, however, suggest that it may be necessary to consider non-biting arthropods as possible vectors of yellow fever. In the first place, it has been found possible to infect monkeys with yellow fever by the alimentary canal. When yellow fever virus was introduced by means of a soft catheter into the stomachs of Indian monkeys (*Macaca mulatta*) and African monkeys (*Cercopithecus aethiops*), the virus passed into the blood stream and, in the case of Indian monkeys, caused fatal infection. Similar attempts to infect by the alimentary tract failed in man, dog, rabbit, guinea pig, rat, mouse, hen and pigeon. In the second place, it has been shown that when yellow fever virus is injected into the abdomen of the cockroach, *Blattella germanica*, kept at 19° C., the virus retains its activity certainly for fifteen days. Though it is not suggested that the cockroach necessarily plays any part in the epidemiology of yellow fever, it has long been known that both African and South American monkeys supplement their mainly vegetarian diet by grubs and insects. Precise data as to the insects eaten are, however, lacking; but in view of the observations described, it would be of considerable interest to determine what animal foods are actually eaten under natural conditions by monkeys in the yellow fever areas of Africa and South America.

Kinetochore or Centromere?

Few questions in cytological terminology can have caused more disagreement and disorder than that of the name to be applied to the portion of the chromosome which determines its movements on the spindle. The names given to this body have been many, and Dr. Schrader's appeal¹ for the general adoption of one term, with the abandonment of all others, must be received sympathetically by cytologists and geneticists. He proposes, however, the

adoption of the term 'kinetochore', saying that it has been employed by Sharp in his text-book². Sharp certainly recommends the term in a footnote, but he has not, so far as I can observe, carried out his own recommendation. Schrader's alternative proposal is to introduce yet another new term.

Where there exist two or more names for an organ, it is generally found that one of them gradually ousts the rest and becomes established as the accepted term. This process of selection may be seen at work in the special case to which Schrader directs attention. Of the innumerable names which have been proposed, only two main forms appear commonly in present-day literature. One of these, the old term 'spindle fibre attachment', with its variants, is clumsy, somewhat misleading and highly inadaptible. Doubtless it will be discarded in time. The other, Darlington's 'centromere', implies a visible particle instead of a dubious relationship, and has many advantages, being intelligible, pronounceable and adaptable. The adjectives 'acentric', 'dicentric', etc., which are so easily derived from the name 'centromere' add materially to its value. There can be little doubt that it is the best term in use to-day. Dr. Schrader would appear to agree with this statement, as of all the terms he wishes to discard, 'centromere' is the only one for the rejection of which he gives detailed reasons. These are two: (1) that the word has been used earlier in a different connexion by Waldayer, and (2) that 'centromere' is likely to be confused with 'centrosome', 'centriole', etc.

Now Wilson's glossary, so long ago as 1925³, gives Waldayer's usage as obsolete, so the first objection can carry little weight. Secondly, the confusion between 'centromere', 'centrosome', etc., is likely to be no greater than that between 'chromomere', 'chromosome', 'chromatin', 'chromatid' and 'chromonema', all of which are in common use to-day and do not, so far as I am aware, cause any serious difficulty. The lack of weight of Schrader's objections is further shown by the growing popularity of the term 'centromere'. Since its inception in 1936, it has come to be used not only by the English authors admitted by Schrader, but also by many others. In recent papers, Muller⁴, Sax⁵, Stone⁶, Kostoff⁷, Geitler⁸, Levan⁹, Sató¹⁰, Klingstedt¹¹, Husted¹², Matthey¹³ and Parthasarathy¹⁴ all employ this name, some for cytological and others for genetical purposes.

Thus it appears that Darlington's term is doing all that Schrader desires. Its use is growing rapidly, and we may look forward with reasonable confidence to the time when, by its own merits, it will have replaced the ten or more other names. To introduce 'kinetochore', or some entirely new word, would be to confound further the present confusion and to delay the achievement of the unanimity which Schrader so reasonably advocates.

Points from Foregoing Letters

THE radium content of sea water is found by E. Föyn, B. Karlik, Prof. H. Pettersson and E. Rona to vary between 0.03 and 0.2×10^{-12} gm. per litre. Even the larger figure corresponds to only about one fifth the amount to be expected from the uranium present in sea water (2×10^{-4} gm. per litre), and the authors consider that the larger part of the radium (or rather its parent ionium) is precipitated together with iron in clays and other marine deposits. The same occurs to a lesser extent with thorium, of which only half the expected amount is found in the sea water.

By bombarding a uranium-lined ionization chamber, connected to a linear amplifier, with neutrons from a radium-beryllium source, Dr. O. R. Frisch has been able to detect ionizing particles of atomic weight of at least seventy. This indicates a break-up of the uranium nuclei into parts of comparable size, as foreshadowed by the experiments of Hahn and Strassmann.

Dr. H. J. Bhabha argues that the fundamental length determined by the mass of the mesotron (meson) does not set a limit to the accuracy of quantum mechanics and that it is possible to calculate the production of large nuclear explosions, to a high degree of accuracy, by treating the meson field quantities classically.

Prof. V. Henri and Dr. E. Bergmann report that 9-cyclohexenyl-phenanthrene and 9, 9'-diphenanthryl show a spectrum practically identical with that of phenanthrene, while 9-cyclopentenyl-phenanthrene, in spite of its similar structure, has a much more diffuse spectrum. An analogous difference between these compounds is found in their chemical behaviour.

Dr. W. O. Williamson indicates a simple process for obtaining titanium dioxide which shows rapid darkening in daylight.

Photographs obtained with the electron microscope are submitted by Dr. M. Benjamin and R. O. Jenkins showing that within the temperature range of $1,000$ – $1,050^\circ$ K. barium spreads uniformly over the surface of molybdenum wires. Above $1,050^\circ$ K., barium evaporates rapidly.

Vitamin B_1 (thiamin) brings about the combination of inorganic phosphate with adenylic acid, when pyruvic acid is present (both in the presence and absence of air), according to experiments by Prof. F. Lipmann. The dehydrogenation of pyruvic to acetic acid (through the agency of thiamin pyrophosphate) supplies the energy necessary for the phosphorylation of adenylic acid. This newly discovered coupled reaction may be of importance as a source of muscular energy, and may account for the effect of vitamin B_1 on the heart.

A. E. Axelrod and Prof. C. A. Elvehjem state that they have shown a decrease in the coenzyme content of the liver and muscle of pigs and dogs deficient in nicotinic acid.

Experiments with rats carried out by Prof. B. Zondek indicate that when the sex hormone, progesterone, is injected into the organism, it is progressively inactivated; four fifths of the quantity injected disappeared within 24 hours, although the physiological effects of the hormone upon the organism only occur 100 hours after injection.

Polarographic curves (obtained with a dropping mercury electrode) of extracts of anterior pituitary lobe are submitted by Prof. H. Handovsky and L. Hauss, indicating the presence of three reducible substances or groups, with oxidation-reduction potentials of $rH = -0.23$, -1.00 and -1.65 volts respectively. From these and other experiments the authors conclude that in extracts from freshly prepared powdered anterior lobe of the pituitary the gonadotropic hormone is always accompanied by a reducible group of $rH = 0.23$ v. and the thyrotropic hormone by a reducible group of $rH = -1.65$ v.

Commenting on Dr. H. L. A. Tarr's communication on trimethylamine in spoiling fish, Dr. J. M. Shewan states that in haddocks preserved in ice the increase in the amount of trimethylamine may be considered a useful guide of the extent of spoilage.

Although the evolution of small amounts of carbon dioxide from polysaccharides on boiling with 12 per cent hydrochloric acid cannot be taken as evidence of the presence of uronic groupings, according to Prof. A. G. Norman, the determination of the rate of evolution under standard conditions may make it possible to decide their presence or absence. Carbon dioxide is liberated at different rates from polyuronides, and from sugars or polysaccharides not containing uronic groups.

Prof. R. W. Ditchburn discusses a visual method for testing vitamin A deficiency, with special reference to certain precautions necessary to obtain reliable results.

Prof. Henry Cohen and Miss Sarah Davies discuss the properties of extracts of the choroid plexus in different species. They find that in the chick this extract increases the permeability of the myelencephalic roof and they suggest that the secretion of the choroidal epithelium is the factor initiating the periaxial spread of cerebrospinal fluid in the embryo.

Observations by Dr. C. G. Dobbs show that when the sporangia of *Mucors* burst in air they give rise to 'sporangial drops' which dry down into solid spore masses. Spores are not liberated directly into the air, as figured in many text-books.

By reducing the exposure to sunlight of pea-plants previously exposed to the normal amount of daylight, Dr. T. H. Strong and Dr. H. C. Trumble have been able to confirm the excretion of nitrogen by the roots of these leguminous plants, as discovered by Virtanen.

A method is indicated by Dr. L. Halberstaedter and Dr. L. Doljanaki for the separation of virus from living cells in cultures of Rous sarcoma *in vitro* by means of irradiation with radium. It has been possible to transform *in vitro* normal tissue into typical Rous sarcoma colonies through the action of agent freed from living cells by means of radium rays. From this it is concluded that, in the usual method of cultivation of the Rous sarcoma *in vitro*, there takes place a constant transformation of the added normal tissue into Rous sarcoma, in addition to the multiplication of the original Rous sarcoma cells themselves. Fibroblasts in pure culture too, may, under given conditions, undergo transformation into sarcoma cells through the action of agent.

Obituary Notices

Prof. Henry Balfour, F.R.S.

In Spencer's 'Last Journey' (Oxford, Clarendon Press, 1931), Plate II, will be seen the reproduction of a photograph of Moseley's 1884 biology class at Oxford. The strikingly handsome young man at the very back of the group—he may be distinguished by the rabbit that he is holding in his hand—is Henry Balfour; Baldwin Spencer, Bourne, Hickson, Roth, and other contemporaries also figuring there. That was a momentous year for Balfour, because Moseley induced him, together with Spencer, to help to arrange the collections just then bestowed on the University by General P. H. Rivers at the instance of his friend Tylor. Nine years later, Balfour was appointed curator of the Museum that had meanwhile been fitted out to house and display the rapidly increasing array of ethnological material; and for the forty-six years to come presided, more or less despotically, over the destinies of a treasure-house henceforth filled to bursting point with the spoil of the primitive world.

Though he never limited the range of his biological interests, and numbered both ornithology and geographical exploration among his enthusiasms, Balfour stuck indefatigably to his main business of studying the earlier arts and crafts of mankind according to the comparative method. He had indeed inherited from Pitt-Rivers and Tylor a system of classification somewhat apt to suggest that evolution is a unilinear process. Yet Balfour himself was never under any illusion as to the vagaries attending the propagation of culture, whether technologically considered or in general. Thus his numerous papers—would that he had found the time to compose a systematic treatise on the subject—are primarily concerned with problems of distribution. Before origins can be determined, he would argue, and in order to settle once for all the parts severally played by borrowing and by independent invention, let us exhaustively chart the actual positions in time and space that the evidence enables us to assign to each of our hypothetical types.

Though rarities may gladden the heart of the keeper of a museum, the scientific value as such of Balfour's acquisitions consists rather in a well-authenticated *provenance* warranting their inclusion in some homologous series. Thus when from 1908 onwards Oxford maintained a diploma course in anthropology under the direction of a triumvirate of whom Balfour was one, he fully justified as a lecturer his claim that, despite the wide scope of the physical and social branches of the subject, technology should have strict parity; for he could exploit the educational possibilities of this *tertium quid* as well as any man of his time. Though in the matter of prehistoric archaeology his museum had to share honours with the Ashmolean, he controlled enough material to be able to demonstrate the relations between ancient and modern prehistory; and indeed nowhere was

the doctrine of the age-long continuity of human development better supported by ocular proofs.

To speak of Oxford's debt to Balfour is partly a domestic matter, and, in view of the financial aid forthcoming from the University, it is better not to inquire into the extent of his private benefactions, if indeed Alma Mater can blush. But it is public knowledge that his exploration of the implementiferous gravels of the Victoria Falls, or, again, his travels in Australia, Assam, West Africa and elsewhere, whence his friends so willingly consented to have their pockets picked, made his show-cases the envy of rival institutions. For he had that flair which must ever be the supreme gift of the collector, and could tell at a glance the precise worth, in a scientific and no merely commercial sense, of each scattered piece of material evidence which presently would be fitted into some mosaic revealing a distinctive pattern. Extremely critical, he was slow to construct; but in the independent way of the Scot he could be very tenacious of a formed opinion, if only because of the sufficiency of the knowledge on which it rested. Moreover, his mind had a strong ally in his hand; for he drew beautifully, and had a sound working acquaintance with primitive processes of all kinds, from fire-making to flint-knapping. Altogether, he was a master of his trade, and there are not many like him in the world to provide a fit successor. For the rest he was a very gallant gentleman, whose candid and courteous nature endeared him to his many friends.

Balfour died on February 9 at the age of seventy-six years.

R. R. MARSH.

Prof. Gustav Tammann

We regret to announce the death in Göttingen at the age of seventy-eight years of Geheimrat Prof. Gustav Tammann, whose researches in the Universities of Dorpat-Jurjew and Göttingen on metallography and the properties of the crystalline and amorphous states of matter have proved to be of far-reaching importance both to pure science and to the metallurgical and glass industries.

Tammann began his life's work after the main laws of heterogeneous equilibria had been propounded by Willard Gibbs and developed by Roozeboom, and his contribution has been that of providing the systematic experimental knowledge and detailed interpretation of heterogeneous systems necessary to establish the thermodynamical reasoning in men's minds as of some value in everyday affairs. One of his first interests was the study of the discontinuities arising during the changes of state in condensed systems, and he devised experimental technique for following such changes over a wide range of temperatures and up to pressures of 10,000 kgm. One of his noteworthy discoveries in this field was that ice,

under high pressure, could occur in several different crystalline forms.

In his search for generalizations concerning the equilibria between solids and liquids, Tammann carried out investigations on supercooled liquids, and these led to fundamental discoveries on the nature of glasses. He measured the rates of crystallization and rates of appearance of nuclei in supercooled liquids, and correlated these properties with the rate of development of heat and the changes in viscosity that occurred. His work on silicates in the crystalline and amorphous conditions has also been of value in pointing the way for the development of geochemical and geophysical ideas.

Tammann is, perhaps, best known for his work on metallography, for the reason that this branch of his activities has had the more immediate practical application. Combining microscopical investigation with the determination of the melting point curves of metallic systems, he laid bare the secrets of many two- and three-component systems, and many inter-metallic compounds. He investigated the internal structures of metallic alloys, their electrical and magnetic properties and the changes in properties which occur on cold working and during recrystallization. His work on the amorphous state led him to appreciate the significance of order and disorder in the crystalline state, and he was the first to show that the chemical properties of solid solutions were dependent on the arrangement of the atoms in the lattice. His conclusions in this field have formed the basis of much modern theoretical work, and have proved of very great significance in the metallurgical industries.

As a teacher of physical and inorganic chemistry, Tammann's influence has permeated the scientific world. Throughout a very long life, he had a very large research school, in which were represented many students from far afield, and his monographs under the titles "Kristallisieren und Schmelzen", "Metallographie" and "Aggregatzustände" led to many developments in other hands. His interest in chemical industry was shown by the numerous technological discussions in which he took part, and by the trend of his metallographical work. He played a very active part in the development of the *Zeitschrift für physikalische Chemie*, the *Zeitschrift für anorganische Chemie* and the Bunsen Gesellschaft. His work was recognized by numerous honours both at home and abroad, and in his seventy-fifth year he was awarded the Adlerschild of the German Reich, with the inscription "Altmeister der Deutschen Metallurgie". By future generations, he will be remembered by his contributions to the development of the practical arts, and in this respect he deserves to rank with Agricola, the renowned metallurgist of the sixteenth century.

W. E. G.

Dr. J. E. R. Constable

THE sudden death of Dr. J. E. R. Constable on February 3 came as a great shock to his friends. Dr. Constable, who was only thirty-two years old,

was a senior scholar at Trinity College, Cambridge, and obtained first class in both Parts I and II of the Natural Sciences Tripos. Thereafter, he spent three years as a research student at the Cavendish Laboratory, mainly devoting himself to the application of electrical methods of detecting single particles, in the study of the artificial disintegration of the elements, work necessitating much patience and sound judgment. This investigation brought him his Ph.D.

In 1931, Constable joined the staff of the National Physical Laboratory, where he was attached to the Sound Section of the Physics Department. He soon proved himself a valuable member of the team of acoustical workers who were endeavouring to unravel the entangled phenomena associated with building acoustics, more particularly as regards the transmission and abatement of noise, both air-borne and impact.

Constable was an ingenious and all-round physicist with an original and receptive outlook. His energy and enthusiasm were contagious: he had a great aptitude for getting things done, and could speedily improvise effective equipment and demonstrations. He revealed a cheery and agreeable freshness of style when lecturing or expounding a paper. When he died, as he did in full harness, he had a book approaching completion; and some twenty published papers and articles, singly or jointly, stood to his credit, most of them relating to building acoustics. One may perhaps refer to his valuable and eminently practical investigations on the optimum sound insulation of double windows and composite partitions; the influence of the obliquity of an incident sound beam on the insulating value of a solid partition; the vibration patterns of walls when transmitting sound; the flanking conduction of sound from room to room in a building; and the reduction of noise transmitted along water pipes.

There was assuredly a successful career in front of Constable, had he been spared. I write with a sense of keen personal loss, for we had done much together. This loss is shared by all his colleagues, who will long remember with affection his frank and friendly disposition and his very likeable personality. We offer our profound sympathy to his widow who, herself a former research student at the Cavendish Laboratory, actively co-operated in her husband's acoustical interests. There is one young son.

G. W. C. KAYE.

WE regret to announce the following deaths:

Prof. Karl Schröter, emeritus professor of botany in the Federal College of Technology, Zurich, aged eighty-four years.

Prof. A. Smithells, O.M.G., F.R.S., emeritus professor of chemistry in the University of Leeds, director of the Salters' Institute of Industrial Chemistry during 1923-1937, on February 8, aged seventy-eight years.

Prof. S. P. L. Sørensen, director of the Chemical Department of the Carlsberg Laboratory, Copenhagen, honorary fellow of the Chemical Society, aged seventy-one years.
